Table 3. Accelerators for zinc phosphate processes

Accelerator	Method of application	Use			Coating weight, g/m^2
		Painting	Cold forming	Oiling	
Nitrite	spray, dip	+			1.5 – 4
	dip		+	+	5 – 15
Nitrate	dip		+	+	10 – 40
Chlorate	dip	+	+	+	3 – 8
Chlorate and nitrite	spray	+			1.5 – 3
Peroxide	spray	+			1.5 – 3
Organic nitro compounds	spray, dip	+			1.3 – 4
Hydroxylamine	dip	+			1.3 – 4
Nitroguanidine	spray, dip	+			1.5 – 5

Coating Formation. Metal dissolution in the pickling reaction results in a significant increase of the pH within the concentration boundary layer close to the metal surface. As a consequence, the equilibrium constant (Eq. 12) for the precipitation reaction is exceeded and zinc phosphate is precipitated. Since the metal surface offers many favorable nucleation sites (there are indications of epitaxial growth [21]), a phosphate coating forms. It ceases to grow further as soon as the metal surface is completely covered because metal oxidation ceases, and the pH within the boundary layer no longer increases. (Eqs. 1 – 4).

The mechanism demands that phosphating solutions be close to the equilibrium as given by the solubility constant of the precipitated phosphate. In spray applications slightly supersaturated solutions are common, whereas dip processes use solutions that are slightly (for low coating weights) to moderately more acidic (for heavy coating weights) than the equilibrium values.

Complex formation. When coating aluminum, fluoride ions must be available for complex formation (Eq. 7), since Al^{3+} ions in concentrations as low as 3 mg/L prevent the formation of zinc phosphate coatings. If different metals including aluminum are to be treated, use of fluoride-free phosphating solutions may allow phosphating of steel or zinc without coating the aluminum.

Sludge Formation. Dissolved Fe^{3+} and $AlF_6{}^{3-}$ ions from the pickling reaction are not enriched in the phosphating solution but are precipitated as iron(III) phosphate (Eq. 10) or trisodium hexafluoroaluminate (Eq. 11), respectively. When treating galvanized surfaces and in spraying processes, relatively small amounts of tertiary zinc phosphate sludge are formed as well.

Figure 10. Scanning electron micrographs of phosphate coatings on steel A) Iron phosphate, spray; B) Manganese phosphate, immersion; C) Zinc phosphate, immersion; D) Zinc calcium phosphate, immersion; E) Low zinc phosphate, immersion; F) Low zinc phosphate, spray

Nitrate-accelerated processes often do not involve sludge formation. Iron(II) nitrate accumulates until an equilibrium is reached between iron dissolution and dragout. (Dragout denotes the solution that adheres to the treated parts and is carried over into the next treatment stage.)

Newer Processes for Zinc Phosphating. Zinc phosphating carried out prior to painting (prepaint process) can be classified as high-zinc or low-zinc processes. High-zinc processes operate at 3 – 4 g/L Zn^{2+}, and low-zinc processes at 0.7 – 1.5 g/L Zn^{2+}, the upper limit for dip applications. Low zinc concentration, i.e., high phosphate to zinc ratio, improves corrosion protection. Coatings on steel produced by low-zinc processes consist mainly of phosphophyllite and show superior paint-base performance to the high-zinc processes with their hopeite coatings [22]. Layer performance is further increased with the introduction of trication processes, which make use of the elements zinc, nickel, and manganese, both in solution and in the coating [23]. Consequently, these processes have become standard pretreatment in, for example, the automotive industry.

Low-temperature processes for cold forming are accelerated by nitrate, and the iron(III) concentration in the bath is limited to 5 – 8 g/L, owing to oxidation with air, preferably performed continuously in a separate reaction tank. Operating temperature has thus been lowered by ca. 30 to 50 – 60 °C [24], and the phosphating tank remains virtually free of sludge.

Health and environmental concerns have promoted the development of

- *Nitrite-free processes* with hydroxylamine [25], nitroguanidine, or hydrogen peroxide as accelerator [26, 27], the last-named offering the additional benefit that its reaction product, H_2O, is of no concern whatsoever.
- *Nickel-free processes* [28, 29].
- *Chromium-free* after-rinses based on organotitanium [30], inorganic zirconium [31], or polymeric compounds [32].
- *Effluent-free phosphating* lines using ultrafiltration for cleaning, hydrogen peroxide acceleration in phosphating, and precipitation plus ion exchange for chromium-free after-rinses, without compromising the performance of the painted parts [26]

Other phosphating processes are summarized in Table 2. Various phosphate coatings are shown in Figure 10.

Iron phosphating processes may not require acceleration. The coating weight varies with the bath composition. Coatings formed on ferrous surfaces contain iron oxides and phosphates. Iron phosphating solutions normally contain surfactants for cleaning, and soiled surfaces may thus be treated in one step (cleaner – coater).

Manganese phosphating processes are performed by dipping only, and iron(II) nitrate is often used for acceleration.

3.2. Methods of Application

The phosphating solutions are generally applied by spraying or by immersion depending on the number, size, and shape of the parts to be treated. The type of application may lead to differences in the composition and morphology of phosphate coatings (Fig. 10).

Strip is also coated by the roll-on, dry-in-place process, in which phosphating solution is applied to the strip and, without rinsing, is dried to form the phosphate coating.

Although phosphating is the crucial step in chemical pretreatment of metal surfaces, other steps may be necessary to complete the process cycle:

1) Degreasing and cleaning to remove oils, fats, and dirt
2) Rinsing with water
3) Pickling to remove rust or other oxides
4) Rinsing with water
5) Activation with hot water or with titanium or manganese phosphate dispersions to induce the formation of a fine-grain phosphate coating in the subsequent step
6) Phosphating
7) Rinsing with water
8) Final rinsing with deionized water (may contain corrosion inhibitors)

Rinsing with water is needed between the processing stages to prevent excessive contamination of treatment baths by preceding solutions.

3.3. Uses of Phosphate Coatings

Corrosion-Protection and Prevention of Red Rust. Heavy zinc and manganese phosphate coatings together with an anticorrosive oil provide substantial protection against corrosion (Fig. 11). Nuts, screws, bolts, and tubes are protected in this way.

Figure 11. Zinc phosphating: corrosion protection in the salt spray test
Hatched: without oil; Full: with oil

Bearing Surface Lubrication. The presence of a crystalline manganese phosphate coating improves the formation of a uniform lubricant film on load-bearing surfaces. It provides some basic lubrication even if the supply of organic lubricant is interrupted. It also helps

to overcome surface irregularities and surface roughness, thus shortening the running-in period of gears and engines. Manganese phosphate coatings are therefore used for engine parts such as pinions, camshafts, pistons, gears, and valves.

Cold Forming. Cold forming of metals involves very high surface stresses. Under these conditions metal-to-metal contact may occur, damaging the workpiece and increasing tool wear. Phosphate coatings provide an effective barrier between metal and tool. Coating weight varies between 3 – 5 g/m^2 for light deformations, such as a calibration pass on a tube and 20 – 40 g/m^2 for heavy cold forging or cold extrusion. In addition, phosphate coatings retain more lubricant and may form highly lubricating zinc stearate coatings when treated with reactive soap lubricants. Phosphate coatings are used in all types of cold forming operations, i.e., drawing of wire, tube, or profile; deep drawing; cold heading; cold extrusion; and cold forging. Steel strip is zinc phosphated and treated with reactive soap. Electrogalvanized and hot dip galvanized steel strip is zinc phosphated in the galvanizing line to improve formability in subsequent drawing operations.

Paint Base. Phosphating enhances the adhesion and corrosion protection of paints. For automotive applications, zinc phosphate coatings of the low-zinc, manganese-modified type offer distinct advantages such as stone-chipping resistance and wet adhesion on galvanized substrates. For powder coatings, iron phosphate often gives optimum results. Figure 12 demonstrates results for a water-based paint system.

Special Uses. Special phosphating processes are used for a number of applications:

Electrical Insulation. Phosphate layers have been used to coat the silicon steel sheets forming the cores of electric motors, generators, or transformers. The insulation provided by a phosphate coating of thickness 1 – 6 μm is sufficient to prevent eddy currents.

Coil Coating. Chlorate-accelerated iron phosphate processes are commonly employed for the coil coating of steel strip; zinc phosphate processes are used for galvanized strip. The pretreatment considerably improves adhesion, which is essential during the forming operation, as well as corrosion protection of the paint film or plastic laminate.

Nickel Phosphating Prior to Vitreous Enameling. Nickel phosphating can replace chemical nickel coating as a pretreatment for vitreous enameling. In this way the number of process steps and the amount of nickel-containing solid waste can be considerably reduced [33].

4. Case Hardening of Ferrous Metals

Parts and components are subjected to mechanical strain and stress, must resist shock and impact, and are affected by wear and corrosion in chemically, thermally or mechanically demanding environments. These stresses are at a maximum at a component's surface. To increase a component's resistance to fatigue, wear, and, in some cases, corrosion, case hardening is applied to obtain a surface layer several micrometers to several millimeters in thickness in which the substrate's hardness is increased significantly, whereas the substrate itself retains its toughness and ductility [34].

The term "case hardening" refers to quite different processes and treatments which have

in common that solely surface hardness is increased to provide increased fatigue strength and wear resistance and, depending on the chemical composition of the surface layer, corrosion resistance.

Surfaces with a high hardness can be produced by two methods:

1) If the component is composed of a "hardenable material (e.g., steel), the surface can be treated thermally (i.e., by short-term heating and subsequent quenching); no chemical reaction via the phase boundary is involved. (see Section 4.1).
2) Otherwise, additional elements can be embedded in the surface region by thermochemical treatment, i.e., thermal treatment in a chemically reactive environment, which can be gaseous, liquid, or solid and releases these elements by chemical reaction at the phase boundary and diffusion into the substrate.

Whereas both processes increase the substrate's surface hardness, owing to modified structure in terms of chemical or phase composition, alternatively hard coatings can be applied by means of chemical vapor deposition (CVD), physical vapor deposition (PVD), ion implantation processes (→ Thin Films), in various gas phases at ambient or reduced pressure; by spraying (Chap. Thermal Spraying), by electrochemical and electroless chemical processes, and electroplating in the liquid phase (→ Electrochemistry → Electrochemical and Chemical Deposition).

4.1. Case Hardening without Chemical Reaction via Phase Boundary

The steel base material must be hardenable, i.e., it should contain at least 0.35 wt % of carbon. Alloyed and unalloyed steels with a limited range of carbon content and good casting qualities are generally used, mostly in the as-tempered condition. Surface hardening may be followed by tempering, if necessary at low temperature.

Iron exists in a body-centered cubic modification (α-Fe, bcc) and a face-centered cubic modification (γ-Fe, fcc); ferrite is a solid solution of carbon in α-iron; austenite is the solid solution of carbon in γ-iron, with a significantly higher solubility. During hardening, steel is first heated to a temperature above A_{c3} (i.e., the temperature at which the $\alpha \rightarrow \gamma$ phase transition occurs) and then quenched (cooled rapidly). Above the transition temperature, carbon present as iron carbide Fe_3C, or cementite, dissolves because of the higher solubility of carbon in γ-iron. During rapid quenching, iron carbide precipitation cannot be completed because the precipitation rate is limited by diffusion. This leads to an extremely hard structure by the name of martensite, which is not favorable as substrate because of its brittleness. If, however, the transition temperature is reached only in the surface region of a steel substrate, owing to an extremely high heating rate, then only the surface will be heat-affected, i.e., hardened. As long as the hardened layer is thin, the internal (compressive) stresses remain bearable, and the desired result is a fatigue- and wear-resistant hard surface on the tough, ductile base material.

Thus, a precise heating technology providing high energy fluxes is crucial for successful case hardening. This is achieved by immersing the components in salt and metal baths, conductive or inductive heating, and heating by plasma, electron, and laser beams. The most important processes are described below.

Subsequent quenching must be performed with a high cooling rate, externally (immersion in or spraying with cooling media) or by the conduction of heat to the interior of the workpiece ("self-quenching").

Of the methods described here, flame hardening is the oldest, but is still widely used. The induction hardening process is the most widely used. Laser hardening and electron-beam hardening, in particular, are more recent developments. Table 4 lists some important process parameters for these techniques.

4.1.1. Flame Hardening

In flame hardening, heating is carried out with gas burners fuelled with a mixture of oxygen and natural gas, propane, or acetylene. Depending on the shape of the workpiece and on the fuel gas, various burner types can be used (e.g., nozzles, slots, and holes) that are arranged in a flat, circular, or contoured formation. Quenching is performed by water spraying or immersion in a vessel.

Table 4. Important process parameters

Parameter	Heating with gas burner	Induction	Laser beam	Electron beam
Energy flux, W/cm				
max.	6×10^3	10^4	10^{10}	10^8 – 10^{11}
used for hardening	$(1-6)\times10^3$	$10-10^4$	10^3 – 10^4 (10^5)	
Heating rate, K/s				
max.	10^2	10^4	10^{10}	10^9 (10^{10})
typical for hardening	10^2	$10-10^4$	10^3 – 10^4 (10^5)	10^3 – 10^4 (10^5)
Quenching	dipping or spraying	dipping or spraying	self-quenching	self-quenching
Thickness of hardened layer, mm	1.5 – 15	0.3 – 20*	0.01 – 1 (2)	0.1 – 1 (2)
Energy supply mode	continuous	continuous	continuous or pulsed	continuous or pulsed
Efficiency, %	50 – 70	50 – 70	70 – 90 (5 – 10)	70 – 80

* Dependent on frequency.

Two basic types of flame hardening process are used; a large number of variations exists. In *progressive hardening*, material is heated trackwise by a moving flame and is then immediately quenched; the burner and quenchant nozzle are designed as a unit [35, 36]. In *spot hardening* the entire surface area is first heated and then quenched. The problem of overlapping tracks in continuous hardening is discussed in Section 4.1.3.

Flame hardening provides case depths of 2 – 10 mm and is performed with a high degree of automation; it can still compete with more recent processes.

4.1.2. Induction Hardening

In induction hardening, heating is achieved by means of electromagnetic induction. An alternating magnetic field is produced when a current-carrying coil induces an alternating current within the workpiece. Direct conversion of electrical into thermal energy leads to heating of the workpiece. The highest temperature is attained in the surface layer owing to the skin effect, and it decreases exponentially towards the core. (The "skin effect" is a physical phenomenon — the current in an electrical conductor is not distributed uniformly throughout the material, but is concentrated in a thin surface layer.) Since the depth of penetration is inversely proportional to the frequency [35]:

Pulsed high frequency, 27 MHz 0.1 mm
High frequency, 400 – 2500 kHz 1 – 0.4 mm
Medium frequency, 3 – 10 kHz 8 – 5 mm

a broader range of case depths can be obtained by induction hardening than by flame hardening.

The shape of the inductor (the tool) matches the shape of the workpiece as closely as feasible; owing to the precise shape and design of the hardening tools, different case depths can be obtained in different areas of a workpiece. Because of the very specific and expensive tool, induction hardening is appropriate for bulk production of parts with complex topography. The inductor is made of pure copper or, for more demanding applications, of silver or sometimes silver-plated copper. Current densities in the inductor can amount to 6000 A/mm^2. Heat losses account for 10 – 25 % of the total power consumption, so internal cooling of the tool is necessary [36]. Quenching is performed with water jets or sprays, and, for small case depths, by self-quenching.

The adaptability of the process has led to the development of many variations, some of which are illustrated in Figure 13. Overlap problems always occur when the continuous-feed process is used (see Section 4.1.3).

During austenitizing, cementite particles of composition Fe_3C, i.e., 6.67 atom% carbon, must dissolve in a matrix with a carbon content of some orders of magnitude lower; diffusion in solids is slow, but a uniform carbon distribution must be achieved after a heating duration of some microseconds. Thus, the hardening result depends strongly on the as-received condition of the base material, that is, with respect to carbide precipitation, particle size, and spatial distributions. To overcome problems with less uniform substrate materials, operating temperatures can be much higher than the phase transition temperature A_{c3} [36]. Induction hardening is a fully developed, highly automated method that is perfectly integrated into production processes.

Figure 13. Methods of induction hardening [36]

4.1.3. Laser Hardening

A laser emits monochromatic, coherent electromagnetic radiation, and the laser beam exhibits nearly no dispersion. The energy density is high, so that an infrared laser is perfectly suited to heat a solid locally and rapidly to high temperature. For metallurgical purposes, carbon dioxide lasers (emission wavelength λ = 10.6 µm) are used. However, reflective metal surfaces absorb only less than 10 % of the emitted energy, which can be enhanced to 35 %. if the surface roughness is increased by, e.g., sand blasting. This is insufficient for practical application, so that black, absorbing coatings (e.g., sprayed graphite coatings) are applied which increase absorption to about 80 % of the emitted energy [37].

Methods such as spot hardening (Fig. 13) are not feasible by laser heating, because the laser beam must be permanently moved. With a continuously operated laser, any required geometrical pattern can be obtained with or without overlapping; pulsed lasers provide local hardening, as dots, small islands, lines, or circles.

However, even if the energy density of a laser beam is uniform along its cross section, and thus enables the corresponding area on the surface of a workpiece to be heated instantaneously to high temperatures, heat is transported within the metal along the temperature gradient by conduction, not only perpendicularly into the core, but also in parallel along the surface. In addition, the metallurgical reactions of steels are not only temperature-, but also time-dependent, especially with respect to rapid heating and cooling. Therefore, the individual laser tracks must not overlap, and the spaces between the tracks are crucial for the hardening result. Lack of process control leads to local overheating, heating durations or quenching rates that differ locally, and unwanted tempering and softening of previously hardened tracks. However, local heat transfer and phase transitions can now be modeled and simulated by finite element methods (FEM), so that individually adjusted motion patterns can be developed for the laser beam, to achieve the designed case depth (or case depth distribution) and microstructures. Consequently, laser hardening is now applied on industrial scale, and its use will presumably increase considerably. With accurate and precise process control complex hardening tasks can be fulfilled, and, in contrast to induction hardening, no expensive tool, individually manufactured for each type of workpiece, is needed.

4.1.4. Electron-Beam Hardening

In electron-beam hardening, impact of an electron beam on the workpiece causes the kinetic energy of the electrons to be converted to heat to a depth of 10 – 50 µm depending on the acceleration energy. Due to the nature of the electron beam, the process must be performed in a vacuum chamber, so that it is somewhat limited with respect to the size of the workpiece. An electron beam can be focused perfectly so that extremely fine or microscopic hardening patterns can be achieved, especially with the appropriate process control. Otherwise, problems of overlapping can occur (see Section 4.1.3). Hardening occurs by self-quenching, and tempering is usually avoided.

Electron-beam hardening is best carried out continuously and gives a case depth of 0.3 –1.5 mm at a track width of up to 50 mm [38]. Industrial application of this process has grown rapidly for mainly two reasons: 1) surface quality unlike in any other process is achieved because of the vacuum, so that the workpieces are not oxidized and remain bright and shiny; 2) high-frequency beam-deflection techniques open up possibilities never attained by other processes, for example, local hardening in workpieces of complex design, e.g. in deep cavities or bores. The treatment sites must not even be directly accessible from the outside.

4.2. Thermochemical Treatment

Thermochemical diffusion processes involve a heterogeneous chemical reaction at the interface of a metal substrate in a reactive environment that may be gaseous (including plasmas), liquid, or solid. The reaction products are in most cases of atomic scale, i.e., small nonmetal atoms, and thus able to diffuse into the substrate and thus modify the composition of the surface layer and the mechanical or chemical properties. Characteristically, the surface layer comprises both components from the reactive environment and from the substrate, and thus problems of defective layer adhesion are avoided.

The uptake of elements from the environment by diffusion can result in the formation of a solid solution with nonmetal atoms present at interstitial sites of the substrate's crystal lattice (diffusion layer), and/or in the formation of intermetallic compounds, in the form of precipitates (precipitation layer), e.g., at grain boundaries, or a closed and uniform surface layer (compound layer).

The thermochemical process follows a multistep mechanism including chemical reaction and transport of matter, mostly by diffusion. If chemical reaction is not kinetically hindered by the presence of passive surface films, diffusion, especially, diffusion in solids, is the slowest and thus rate-determining step. Consequently thickness and composition of the final surface layer depend on temperature and time, besides the concentration gradient and the diffusion coefficient. The residence time of the parts and workpieces in the furnace is generally used to control the resulting layer properties. Residence times can be in the range of minutes (e.g., 20 min) up to many hours (e.g., 100 h). Although higher temperature would enhance diffusion rates significantly, thermochemical treatments are performed at elevated temperatures between 400 and 1200 °C (mostly between 500 and 1000 °C), but within quite small temperature windows because modification of the substrate's microstructure (e.g., phase transition, grain growth, etc.) must be minimized.

The most commonly used thermochemical treatments — gas-phase nitriding and carburizing — are used for steels. Iron has high affinity for both carbon and nitrogen, and is reactive towards compounds like ammonia and hydrocarbons in gas phase. Provided the chromium content of a steel does not exceed 13 wt % (this limit depends on the content of additional alloying elements, especially C), it is not protected by a passive film which might significantly decrease the surface reactivity [39]. Other engineering metals and alloys, e.g., aluminum and titanium do not react readily in the gas phase because of their thermodynamically stable and impenetrable oxide layers. However, aluminum and titanium nitrides and carbides are known for their hardness and wear resistance. Both metals and their alloys can only be treated successfully by using plasma-assisted processes.

4.2.1. Gas Carburizing

4.2.1.1. Principles

Carburizing (carburization) increases the carbon content of the surface zone. Owing to high process temperature above austenitization temperature (A_{c2}) ferritic steels are transformed during the treatment. Diffusion of carbon into the surface zone of a steel with a low carbon content renders this zone hardenable, and it is then quench-hardened. The core of the workpiece remains unaffected, i.e., ductile. A hard, wear-resistant martensitic structure is produced in the surface zone. The process is used on "case-hardening steels", which are either unalloyed or only slightly alloyed, and contain $\leq 0.25\,\%$ carbon. Depending on the original material, the carbon content of the surface zone is 0.6 – 0.9

wt %. The usual layer thickness (the carburization depth, or, after hardening, the case depth) is usually 0.1 – 1.5 mm, less frequently up to 3 mm. As expected for a diffusion process, the carbon concentration decreases gradually from surface to core (Fig. 14, curve a). However, an initially constant carbon content and hence hardness are often required (curve b). This can be achieved by two-stage carburization (see Section 4.2.1.3). Small quantities of nitrogen are often allowed to diffuse along with the carbon (carbonitriding). The nitrogen decreases the temperature at which austenite formation occurs, and the diffusion process therefore takes place at lower temperatures. Workpieces that are susceptible to dimensional changes can then be more gently treated.

4.2.1.2. Properties of Carburized Components

Carburizing is one of the most widely used thermochemical processes. Treated parts have a tough, ductile interior and a hard, wear-resistant surface case with internal compressive stresses promoting layer adhesion and resistance to wear and corrosion cracking, thus improving fatigue strength and life, as well as load-bearing properties.

With carbon contents of > 0.5 wt % in the case after carburizing, some austenite remains after quenching because the end temperature of martensite formation is below room temperature. The amount of retained austenite depends on steel composition, carburizing conditions, and surface carbon content. Retained austenite reduces the internal compressive stresses in the case.

Furthermore, care must be taken to minimize oxidation when the carburizing atmosphere contains oxygen compounds such as water, CO_2, CO, or methanol. Intergranular oxidation occurs within a surface zone of 10 – 15 µm where oxides with aluminum, silicon, manganese, or chromium are formed, preferentially at grain boundaries. Thus, intergranular oxidation leads to microscopic "notches" which can initiate crack formation if the part is subjected to bending, so that fatigue resistance is affected. Furthermore, oxidation removes alloying elements, necessary for hardening, from the matrix. With high-load components, the oxidation zone must be removed by mechanical work.

Figure 14. Carbon (A) and hardness (B) profiles after carburizing
a) One-stage carburizing; b) Two-stage carburizing

4.2.1.3. Carburizing Methods

The carburizing process is carried out mainly in the gas phase, to a lesser extent in a salt bath, and to a very small degree in powder. Developments are proceeding in two directions: use of plasma and use of low pressure, both combined with quenching in high-pressure gas.

Irrespective of the method, the carburizing mechanism is based on diffusion. The results depend not only on treatment temperature and time and the composition of the steel, but also on the characteristics of the carburizing media which affect carbon potential, carbon transfer factor, and carbon availability.

The *carbon potential* is defined as the percentage of carbon taken up by a test piece of pure iron in equilibrium with the carburizing medium

at a specified temperature. The *carbon transfer number* is the amount of carbon taken up from the carburizing medium by a defined surface area of the steel in unit time. The *carbon availability* is a measure of the amount of carbon in the carburizing medium per unit weight or volume.

Gas-Phase Carburizing. Three reactions are involved:

$2\ CO \rightleftharpoons (C) + CO_2$	Boudouard equilibrium
$CO + H_2 \rightleftharpoons (C) + H_2O$	water gas equilibrium
$CH_4 \rightleftharpoons (C) + 2\ H_2$	methane–hydrogen equilibrium

In these equations, (C) signifies the carbon dissolved in the austenite in equilibrium with the surrounding gas. When the carbon-releasing species, CO or CH_4, are not already present in the carburizing gas mixture, they are formed by decomposition in the carburizing furnace or in separate generators. The above equations are of fundamental importance for the measurement and control of the carbon level. Indirect methods of analysis are available such as IR absorption for the carbon dioxide and methane content and dew point determination for the water content. Increasing use has been made of oxygen-potential determination with an oxygen sensor. Direct methods include discontinuous determination of carbon using thin foils of iron, and continuous measurement of electrical conductivity changes in a wire owing to carbon absorption. The latter procedure permits continuous measurement of the most important parameter, the carbon potential [40]. Modern carburizing processes are computer-controlled and thus allow predefined carbon profiles with defined carbon contents, concentration gradients, retained austenite, and so on to be obtained and help to reduce carburizing times by at least 20 %. The profile illustrated in Figure 14 was obtained by using a very high carbon concentration to produce excess carburization of the surface. This was followed by a diffusion stage at a lower carbon concentration, during which the excess carbon leaves the highly carburized zone to give a greater depth of carburization (Fig. 15). This two-stage approach gave the desired carbon profile and shortened the time required for carburization [41].

Gaseous and liquid carburizing media provide such high carbon availability that the feed rate into the furnace must be controlled to avoid excessive carburization or soot formation. These problems can be avoided by using carrier gases that contain little or no carbon. The carbon concentration can be accurately adjusted by addition of carbon monoxide, methane, or propane. In industry the process gas used is "endo(thermic) gas", from the endothermic reaction of air and hydrocarbons, usually from natural gas. Endo gas has the following composition: 20 – 25 vol % CO, $\leq$ 0.5 vol % CO_2, 30 – 45 vol % H_2, $\leq$ 0.5 vol % CH_4, balance N_2. Processes based on nitrogen as carrier gas have been developed, mainly for economic reasons (i.e., shortage of natural gas or electric power) [42].

Figure 15. Carbon profile during two-stage carburizing [40] C_C= core carbon content; C_G= carbon content which determines case depth; C_R= desired case carbon content; C_S= saturation concentration of carbon in austenite; D_1= carburizing depth after first carburization; D_2= carburizing depth after second carburization; F_1= carbon distribution after first carburization; F_2= carbon distribution after second carburization

Liquids can also be used to produce carburizing gas. They can be added directly to the furnace chamber dropwise or by spraying. Alternatively, they may be vaporized in a reactor outside the furnace and led into the furnace as a gas. Lower alcohols (e.g., methanol, ethanol, or 2-propanol), ketones, and esters can also be used [35]. In the carbonitriding process, ammonia is also added as a source of nitrogen.

Past investigations into carburizing at reduced pressure employed methane as carburizing gas. Their aim was to reduce the carburizing time and hence to prevent intergranular oxidation of the case. These goals were not realized,

and the reproducibility and smoothness of the process were not satisfactory [43]. In new developments propane was used instead of methane, and the process was carried out at lower pressure. Acetylene is another possible carbon source. If the reaction gas is oxygen-free then quenching should also maintain oxygen-free conditions. Modern quenching media involve high-pressure gases, such as nitrogen, helium, or hydrogen [44].

As carbon diffusion in the metal controls the overall rate, and does not depend on the carbon source, the carburizing temperature is generally 930 – 950 °C. If the temperature is increased to 1000 °C, the diffusion coefficient of carbon into the steel is doubled, but the grain growth of the steel increases so much that the use of fine-grained steels provides only a partial remedy. (Coarse-grained steels are not as strong as fine-grained steels.) High-temperature carburizing has therefore only been used to a limited extent for large carburizing depths.

Carburizing is carried out in many types of furnaces (e.g., small shaft furnaces, multipurpose chamber furnaces with one or more chambers, and large continuously operating installations). A technical and economical solution is available for each kind of process, size of workpiece, and throughput.

Carburizing in Molten Salt Bath. In carburizing in molten salt baths, alkali metal cyanide is the most efficient carburizing agent. Much research has been aimed at substituting the cyanide with less toxic substances (e.g., carbides), but these salt baths are difficult to handle in practice, and give nonuniform results and poor reproducibility.

The decomposition reaction of cyanide in the salt bath is not yet fully understood, although it is assumed that carbon monoxide certainly acts as the carburizing agent. The reaction byproduct is carbonate.

In modern carburizing baths the cyanide is formed by decomposition, and the baths are initially set up from cyanide-free salts, with addition of a regenerator and an activator ($BaCl_2$) to maintain constant concentration of the active species. The regenerator (a nontoxic polymer) is added continuously to the bath and generates cyanide by reaction with the carbonate byproduct. The cyanide content can be held constant; waste salts are not produced. The achievable carbon content of the case depends on the activation (i.e., the alkaline earth metal chloride concentration). In practice the carbon content of the layer is adjusted by controlling the activator content of the strongly activated bath. Examples of trade names for commercial carburizing baths are Ceconstant and Durofer for regenerable baths, which both give carbon contents of 0.5, 0.8, and 1.1 wt % in the case. As in gas carburizing, a two-stage process aiming at specific carbon depth profiles is feasible, e.g., by performing two-thirds of the treatment in a highly activated bath, and one-third in a weakly activated bath [45].

When the carburized parts are subsequently treated in a warm salt bath, the adhering cyanide is destroyed by oxidation. When other cooling media (water, oil) are used, they must be detoxified afterwards. Modern automated installations include facilities for salt recovery, e.g., by treating the wastewater in an evaporation process.

Carburizing in Powder and Granular Material (Pack Carburizing). Only a small part of carburizing is performed with solid media (powder and granules). The process can be carried out without technical or economic difficulty, especially when a deep case is required. The solid medium consists of a carbon source (usually high-purity charcoal with low sulfur content) and an activator (usually carbonates of the alkali or alkaline earth metals). Activation probably occurs as follows:

$$BaCO_3 \rightarrow BaO + CO_2$$

$$C + CO_2 \rightarrow 2\,CO$$
$$CO + Fe \rightarrow FeC + \tfrac{1}{2}O_2$$
$$CO + \tfrac{1}{2}O_2 \rightarrow CO_2$$

Granules have two advantages over powder: powder tends to separate, and granules have higher gas permeability. Granules are usually formed by mixing the powder with a binder and compressing into shape. On heating the solid medium to 930 – 950 °C, carbon monoxide is formed as a carburizing agent; carburizing thus takes place via the gas phase.

Plasma Carburizing. The development of thermochemical processes involving reactive plasmas started with plasma nitriding, and is de-

scribed in Section 4.2.2.3. The industrial use of plasma carburizing was first reported quite recently [46]. Plasma carburizing is performed in a hot chamber, i.e., external heating is necessary, paraffinic hydrocarbons such as methane are used as reaction gases, and the quenching installation is integrated into the furnace. Controlled carbon distribution should be possible and treatment time is potentially shorter than that for conventional processes. As the reducing gas atmosphere does not contain oxygen compounds, it is possible to minimize intergranular oxidation.

Figure 16. Hardening procedures used after carburization [47]
A) Direct hardening; B) Simple hardening; C) Hardening after isothermal modification; D) Double hardening A_{c1}, A_{c3} = transition points of iron

Hardening. The carburized steel is hardened by quenching in water, oil, or an oil – water emulsion according to one of the processes shown in Figure 16. The most economic method, whenever possible is direct quenching (A), in which the steel retains its original grain size. If, however, the material has a coarse-grained structure (e.g., due to long carburizing times and/or high carburizing temperature), it is first slowly cooled and then reheated (B) to convert it to fine-grained martensite; an isothermal transformation followed by quenching (C) may also be used. The double-hardening (D) process consists of initial hardening at austenite-formation temperature, and then at the lower temperature of the core; this method however is rarely used for economic reasons and because of large dimensional changes [47, 48]. After hardening, case-hardened workpieces are generally tempered at relatively low temperatures before use.

4.2.2. Nitriding and Nitrocarburizing

4.2.2.1. Principles

The term nitriding denotes the uptake of nitrogen into the surface zone of a ferrous metal workpiece. In general, this causes the formation of a case with an external *compound layer* which contains iron nitrides, namely, the ε-nitride, Fe_4N, and the γ'-nitride, $Fe_{2-3}N$. Below the external compound layer is a *diffusion zone* with an interstitial solution of nitrogen in the α-iron lattice; its thickness and concentration gradient depending on treatment temperature and residence time (Fig. 17). As nitriding is performed at slightly lower temperatures than nitrocarburizing the ε-nitride is usually only found after nitrocarburizing. Some alloying elements such as Al, V, Mo, Ti, and Cr form nitrides of their own in the compound layer or enable the formation of nitride precipitates in the diffusion (or precipitation) zone.

Figure 17. Nitrocarburized layer on an unalloyed steel (schematic)
a) Porous zone; b) ε-$Fe_{2-3}N$ layer; c) γ'-Fe_4N layer; d) Diffusion layer (solid solution of nitrogen in iron)

γ'-Iron nitride Fe_4N has a cubic structure and contains 5.7 – 6.1 wt % nitrogen; ε-iron nitride $Fe_{2-3}N$ has a hexagonal structure and contains 7.7 – 11.1 wt % nitrogen. In a dual-phase compound layer γ'-nitride often forms a narrow border between the ε-nitride and the base material or the diffusion zone, which is difficult to identify metallurgically or by X-ray techniques.

In nitrocarburizing both nitrogen and carbon are made to diffuse into the surface layer of a workpiece (see Section 4.2.2.3). The compound layer then additionally contains ca. 0.5 – 2 wt % carbon. Oxygen can be present in amounts up to several weight percent in nitrided or nitrocarburized cases.

The outer part of the compound layer can exhibit a porous structure, like a band of microscopic or submicroscopic pores, or cavities. Some of the cavities are joined to one another and to the surface, but most of them form isolated spheroidal voids with a diameter of < 1 µm. The mechanism of pore formation is not yet fully understood, but higher reaction rates, higher temperatures, and higher nitrogen availabilities must be involved, because pores are found preferably in the ε-nitride after nitrocarburizing, rarely in the γ'-nitride after nitriding, and never in the diffusion layer after prolonged nitriding. Nitriding and nitrocarburizing processes can be controlled by means of the nitrogen-source concentration, reaction temperature, and residence time.

Figure 18. Thickness of compound layers in ferrous materials after nitrocarburizing in a molten salt bath at 580 °C
a) C 15 – C 45 steel; b) Quenched alloy steel; c) Hotworking 12 %-chromium steel, cast iron

The thicknesses of compound layer and diffusion zone are a function of the treatment process, the treatment parameters, and the base material. Figures 18 and 19 show the depths of these layers in various materials as a function of the nitrocarburizing time.

4.2.2.2. Properties of Nitrided and Nitrocarburized Components

Nitriding and nitrocarburizing are quite simple processes. The solid solution of nitrogen in the diffusion layer is seen as responsible for increased fatigue strength, life, and endurance limit, whereas the compound layer provides excellent wear and some corrosion resistance. Consequently, the prominent goal is to produce surface layers perfectly adapted to the technological demands of the workpieces during operation, by improved process control. This can be achieved basically in one nitriding furnace by variation of the process parameters, so that the process result is solely a diffusion zone, or a diffusion zone in combination with a single- or dual-phase compound layer. In contrast to carburizing, in which the carbon content of the surface region is increased in the first step at a temperature above the transformation temperature of the steel, and the case is subsequently hardened by quenching, it is not necessary to quench nitrided parts, basically because no comparable

phase transformations are needed. In addition, distortion is less of a problem for the same reason, namely, the lower reaction temperature.

Fatigue stength and endurance life are improved mostly in the diffusion layer, where hardness increases gradually depending on the local nitrogen content, and with specific compressive stress distribution. It is plausible that the effects of roughness peaks, microcracks, and voids (and the accompanying local stress maxima) are smoothed out during nitrogen uptake by the slow expansion and growth of the diffusion zone. Consequently, fatigue strength and life, especially of notch-sensitive steels, are improved.

Figure 20. Results of laboratory wear tests (adhesive wear, pin – disk method) [49]
a) C45, hardened and tempered; b) 42CrMo4, nitrocarburized; c) 42CrMo4, borided; d) C100, vanadized

Adhesive wear is caused by metal-to-metal contact and cold welding, and is largely responsible for wear losses, e.g., in machines and motor vehicles. This type of wear can be very effectively combated by the nitride compound layers obtained by nitrocarburizing. Figure 20 shows the results of laboratory wear tests. In addition, nitrocarburizing also improves fatigue strength, the best results being obtained for components with unalloyed or low-alloy steels with high notch sensitivities. Finally, nitrocarburizing in combination with controlled cooling or quenching in specific atmospheres or media provides corrosion protection that can surpass that of electroplated surfaces or electroless coatings. Figure 21 shows the results of some corrosion tests [50].

In industrial application, nitriding and nitrocarburizing processes seem to de developing in different directions, for different demands and applications. Whereas nitriding is applied to form diffusion layers while avoiding nitride formation, for improved fatigue properties, nitrocarburizing is used to form compound layers providing wear and corrosion resistance. Thus, industrial nitriding processes are performed at lower temperatures and at residence times orders of magnitude greater than nitrocarburizing processes. The aim of nitriding is to obtain diffusion layers without compound formation, whereas the objectives of nitrocarburizing are highly specific single- or dual-phase compound layers without any pores.

4.2.2.3. Nitriding and Nitrocarburizing Methods

All nitriding and nitrocarburizing processes are carried out at fairly low temperatures (450 – 600 °C). Dimensional changes are consequently considerably smaller than with, for example, the carburizing process, which is carried out above the transformation temperature. Originally the maximum treatment temperature for nitriding or nitrocarburizing was the A_1 temperature in the iron – nitrogen system (590 °C) at which α-iron is transformed into γ-iron. Above this temperature an extra phase is formed below the compound layer which consists of nitrogen pearlite (braunite), nitrogen austenite, or nitrogen martensite depending on the base material and quenching conditions. More recently, this limit has been exceeded to reduce the treatment time and make better use of available plant capacity. Although the effect of the extra phase under the compound layer is not yet fully understood, the process is frequently operated at 600 – 650 °C. A precondition for this method is that the components must not be susceptible to distortion.

In all processes, nitrogen must be available in a diffusible form, i.e., the atomic state formed by dissociation, which can be thermal (gas-phase dissociation of ammonia), plasma-assisted (molecular nitrogen), or liquid-phase decomposition of alkali metal cyanate, catalyzed by the metal interface.

Gas nitriding is performed in mixtures of ammonia, nitrogen, and hydrogen, with ammonia being the reactant. The compound layer consists of nitrides of iron and alloying elements with no carbon; it is therefore brittle and unsuitable for many applications. The main aim of gas nitriding is to increase the bearing capacity of the surface zone of the workpiece while maintaining high core strength and small dimensional changes. Treatment is carried out batchwise in externally heated vessels at 480 – 520 °C for 30 – 100 h. Ammonia is catalytically decomposed into atomic nitrogen and hydrogen on the surface of the workpiece.

Appropriate process control enables the formation of a compound layer to be prevented by controlling the composition of the atmosphere. The control parameter is the nitriding number (or index) which is related to the equilibrium constant of ammonia formation (as discussed in the Section page 29). Gas nitriding without compound-layer formation is performed at low nitriding numbers. Thin compound layers formed nevertheless are removed by machining.

Process control is not simple because the composition of the nitriding atmosphere at a given temperature and total pressure depends on gas flow rate and on the catalytic surface area, which includes not only the steel parts but also the interior surface of the furnace; the latter contribution depends on the specific design and condition of the furnace.

Any steel can be nitrided in the gas process, but the achievable surface properties and the nitriding parameters depend strongly on its chemical composition. Thus construction steels with specifications without respect to composition will not exhibit uniform surface properties after nitriding unless they are from the same batch. Special nitriding steels (i.e., steels alloyed with nitride-forming elements such as aluminum, titanium, and chromium) are not widely used. [52]. Workpieces are nitrided in a hardened and tempered condition. Both heating and cooling are performed slowly, so that distortion and dimensional changes are minimized.

The objective to shorten nitriding time and to prevent the formation of compound layers has led to the development of multistage processes. For example, in a two-stage process [52], the first stage uses a nitriding medium with a high concentration of nitrogen, and the second a much lower concentration. Oxygen, water, or water vapor can be added to furnace atmosphere to activate or depassivate the surfaces.

Salt bath nitrocarburizing is performed in a molten salt mixture, typically containing an alkali metal cyanate (NaOCN, KOCN) as active component and 33 % of sodium or potassium carbonate. The cyanate decomposes thermally by the catalytic action of the surface of the workpiece, forming atomic nitrogen which can diffuse through the surface into the workpiece. Carbon in diffusible form is formed simultaneously. The byproduct of the reaction is alkali metal carbonate. Addition of a "regenerator" converts the byproduct carbonate back to cyanate, usually in a continuous process. The regenerator can be a melamine derivative or a urea polymer, though the latter is less active [53]. A side reaction between the cyanate and the workpiece generates a small quantity of cyanide, which must be removed during or after the process (see below).

Treatment is carried out at 570 – 580 °C for 45 – 180 min. The trend is towards higher treatment temperatures. Case depths produced under these conditions are shown in Figure 18.

Gas treatment processes have been highly automated for many years. Automation started later with salt bath processes but has now reached a similar level. A salt bath nitrocarburizing installation consists of precleaning, preheating, nitrocarburizing, quenching, and final cleaning steps. Precleaning is important for the success of the process. Although the salt bath is less sensitive than the gas process in this respect, residues from treatment liquids and washing media can lead to erratic results. In the next stage, the workpiece is preheated to ca. 300 – 350 °C. This avoids too great a reduction in the temperature of the bath when a charge is added to it, and it also ensures that the workpieces are dry when they are introduced into the salt bath. The next stage is the nitrocarburizing bath; several baths may be used to improve the flexibility of

the process. The salt baths are contained in crucibles made of pure titanium or nickel-based materials. Air is blown through the bath to ensure complete mixing and hence a constant composition and temperature. Quenching may be carried out in various ways. Unalloyed steels reach their maximum fatigue strength after quenching in water. Alloy steels are less sensitive in this respect. The quench water must be treated to eliminate its toxic cyanide content. Components which are extremely sensitive to distortion can be transferred from the nitriding bath to a vacuum chamber.

An oxidizing hydroxide bath containing nitrate has been developed for a commonly used quenching process carried out in the temperature range 330 – 400 °C. This bath immediately converts the cyanide and cyanate adhering to the workpiece to carbonate so that it is no longer necessary to detoxify the water used in the subsequent cooling and washing stages. A further advantage is that the stepwise and hence very mild quenching further reduces the tendency to dimensional change. Finally, treatment in the oxidation bath causes surface oxidation of the compound layer, forming a thin layer of Fe_3O_4 which gives good corrosion properties [56].

The corrosion-resistant property of the oxidized compound layer can be improved by a final surface treatment (e.g., vibratory grinding, polishing) and further final oxidation.

The salt bath nitrocarburizing processes described here have become known under the trade names Tenifer, Tufftride, and Melonite. The Sursulf process is also based on the use of alkali metal cyanate and carbonate with small amounts of cyanide. Sulfur is added to the bath to improve the running properties of the workpieces produced. However, the porosity is greatly increased by sulfur addition [55].

Gas Nitrocarburizing. Gas nitrocarburizing involves the diffusion of not only nitrogen but also of carbon, which contributes to the formation of the compound layer. The source of nitrogen is ammonia. To compare and evaluate different nitrocarburizing atmospheres, the nitriding index N has been introduced [57]:

$$N = \frac{p_{NH_3}}{p_{H_2}^{1.5}}$$

The equation for the decomposition of ammonia

$$2\,NH_3 \rightarrow N_2 + 3\,H_2$$

has the equilibrium constant

$$K = \frac{p_{NH_3}^2}{p_{N_2} \cdot p_{H_2}^3}$$

which is related to the nitriding index N by the equation

$$N = K^{0.5} \cdot p_{N_2}^{0.5}$$

An example of the use of the nitriding index N is given in Figure 22, which shows nitrocarburizing conditions in the ternary system Fe – N – C. Process control via the nitriding index N is finding increasing use in industrial practice.

Figure 22. Ranges of formation of nitrides and carbides in the ternary system Fe–C–N at 575 °C [52]

The gases added to the ammonia as a source of carbon can be divided into three groups:

1) Carbon dioxide and carbon-dioxide-rich mixtures
2) Carbon monoxide and carbon-monoxide-rich mixtures
3) Carbon-rich gases

Multistage processes with atmospheres specific for each stage are used in industry.

Carbon dioxide is very suitable as the added gas for nitrocarburizing. For a given degree of dissociation of the ammonia, it increases the nitriding index; carbon is strongly taken up by the compound layer owing to the high carbon activity; and formation of the compound layer is much facilitated. Besides pure carbon dioxide, carbon dioxide – nitrogen mixtures or exo(thermic) gas are often used in practice, sometimes with additional carbon monoxide

and/or hydrogen. Exo gas denotes the reaction product of the near-stoichiometric combustion of hydrocarbons, e.g., natural gas. Approximate compositions are 0 – 3 vol % CO, 10 – 13 vol % CO_2, 0 – 4 vol % H_2, 2 – 3 vol % H_2O, balance N_2. Carbon activity increases with increasing carbon monoxide content.

In theory, carbon monoxide could be used as carbon source, and many references in the literature [57] refer to the use of carbon-rich carrier gases (e.g., methane, propane, and amines). However, neither method is used in practice. Carbon monoxide is added mainly in the form of endo gas, or is produced by pyrolysis of methanol. A commonly used endo gas composition is ca. 20 vol% CO, 35 vol% H_2, and 45 vol% N_2 as a 1:1 mixture with ammonia. The composition of the atmosphere under nitrocarburizing conditions in the furnace is far more complex and difficult to determine.

Gas nitrocarburizing is usually performed at 570 – 580 °C (like the salt bath process), but here also a trend towards higher temperatures exists. The treatment time is also similar to that of the salt bath process, i.e., 90 – 240 min. In general, the gas process takes longer on account of the slower heating.

Gas nitriding is mainly carried out in single-chamber furnaces and batch processes because of nitriding durations around 100 h. In gas nitrocarburizing more types of furnaces are in use, e.g., multiple-chamber installations including quenching chambers, which can be used for other treatments, e.g., carburizing. Installations are operated batchwise or continuously, the latter with residence times down to several minutes. These installations are single-purpose, mostly pusher-type furnaces. Throughput is then in the range of 30 t/d or more.

In all heat-treatment operations, aspects of occupational health and safety must be taken into account. Parts must be dry, and may under no circumstances contain water residues, e.g., enclosed in voids or bores. During gas nitriding or nitrocarburizing with ammonia, ignition may occur if the oxygen concentration in the furnace exceeds the explosion limit and an ignition source is present. However, this danger is difficult to assess because of the lack of information on the composition of the atmosphere. In practice, heating of the parts to process temperature in a batch furnace is performed in an inert atmosphere (i.e., nitrogen) so that the furnace is flushed; continuous processes apply a flame curtain to prevent any oxygen from entering. The exhaust gases are treated by combustion.

Process and furnace development for gas processes depend on developments in measuring and control. As the actual composition of the atmosphere depends on a multitude of parameters, including batch size as well as chamber design and condition, gas analysis of the multiple components is not feasible in practice. Thus various probes and sensors have been developed to assess control parameters such as the nitriding index. Gas probes based on various measuring principles, such as pressure measurement or electrochemical, are available in the market.

Gas-phase processes can be sensitive to passive metal surfaces. This refers to passive surface films, often present on steel parts containing 5 wt % or more chromium. Manufacturing residues (from lubricants, cleaning media, greases, and oils) can present problems, especially if they or their components are nonvolatile at process temperature. The removal of surface contaminants by diligent cleaning prior to heating is essential.

Gas nitrocarburizing processes are referred to by company names that have no relation to the process itself. Examples are Nitroc (ammonia and exo gas, Aichelin, Germany), Nitemp (ammonia and endo gas, Ipsen, USA), Triniding (ammonia and nitrogen, Midland-Ross, USA), and Deganit (two stages: ammonia and exo gas, then ammonia and endo gas, Degussa, Germany).

Plasma Nitriding and Nitrocarburizing. Plasma nitriding is based on the formation of the active, diffusible species from molecular nitrogen by plasma discharge. Unlike nitriding and similar to nitrocarburizing, relatively tough compound layers are formed which are said to be less prone to pore formation than in nitrocarburizing. Thus the plasma-assisted processes aim at the formation of a compound layer, independent of the presence of a carbon source in the reactive atmosphere.

Basically, the workpiece is the cathode inside a vessel which acts as the anode. The reaction gas in the previously evacuated container may simply consist of nitrogen at a pressure of 0.05 – 1 kPa. A potential difference of ca. 100 V is

applied between the vessel and the workpiece, producing a visible glow discharge seam surrounding the surface of the workpiece. Nitriding is assumed to proceed according to the mechanism presented in Fig. 23. The active species consists of reactive atomic and ionized nitrogen, present in the glow discharge seam or boundary layer near the metal surface. Owing to the directed movement of nitrogen ions in the electric field and depending on the potential difference in the boundary layer, iron atoms and ions become mobile and react to form nitrogen-rich iron nitrides, which are assumed to condense at the gas – solid interface. Since these intermediate nitrides are unstable, they decompose and release atomic nitrogen to diffuse into the substrate or to be desorbed into the atmosphere. The nitriding process thus is assumed to consist of cycles of removal and deposition. Direct diffusion of nitrogen from the plasma is said to occur only to a small degree, if at all.

Figure 23. Plasma nitriding reactions [58]

In a d.c. plasma the substrate reaches nitriding temperature (i.e., the temperature needed for diffusion) without additional external heating (cold wall, cold chamber). However, today, because of multiple advantages with respect to uniform layer formation, pulsed plasmas (i.e., plasmas produced with pulsed direct current) are applied. The batch then requires external heating (e.g., by heating the walls of the vessel: hot wall, hot chamber) [59, 60]. Pulsed processes require computer control.

Compared to other nitriding processes plasma nitriding is exemplary for the great variety of modifications with respect to structure and properties of the hard layer. Thus, diffusion layers without any compound layer can be produced, or single-phase compound layers, or dual-phase mixed layers. Plasma nitriding is performed at 350 – 650 °C for 10 min to 48 h. At lower temperatures high core strengths are maintained; dimensional and shape changes are small. Temperatures above 590 °C can be applied, e.g., when thick single-phase γ'-layers are required. Reaction gas is nitrogen with or without methane, which must be supplied premixed from gas bottles or gas-mixing equipment. The gas composition can be adjusted during the process between 80 and 100 % nitrogen.

Similar to the gas processes without plasma assistance, parts and workpieces must be clean to obtain results without defects. Even if plasma activation in argon or oxygen plasmas is applied, passivation owing to thick layers of contaminants or passive oxide cannot be overcome in reasonable time, and there is the danger of contamination of the reaction vessel. Thus, the parts must be thoroughly cleaned prior to plasma treatment, preferably with aqueous cleaning agents. However, passive oxide layers, such as those on stainless steels, are easier to overcome than in the gas processes. Metals and alloys which cannot be treated in the gas phase because of very stable and dense oxide layers, like aluminum and titanium, can be nitrided in reactive plasmas.

Installations for plasma nitriding and nitrocarburizing are relatively simple and consist of a vacuum-tight cylindrical vessel, a system for supplying and mixing the gas, a vacuum system, and an electric power unit. Gas composition is usually controlled not in the reaction vessel but by careful mixing and metering of the gas components.

Up to now, a drawback of the plasma process was the limited size of the vessel and therefore, the workpiece, and the assembly of large batches of bulk parts. Nevertheless, plants are increasingly becoming available, and continuous setups are in development.

Future Developments. The use of nitriding and nitrocarburizing of ferrous components increased considerably during the 1980s, and this trend seems to continue. One reason is that in general more attention is paid to specification of the properties of the parts and the contribution of their surfaces. Especially the relatively low process temperature reduces costs for installation and operation. Recently, even complex processes have become manageable owing to automation, process simulation, and computer control.

The gas nitrocarburizing process accounts for ca. 40 % of the worldwide total, as does the molten salt process. The "classical" gas nitriding process continues to have a constant share of ca. 5 – 10 %. The plasma process makes up the remaining 10 – 12 % but still has some potential for growth.

Further development of the nitriding and nitrocarburizing processes will be in the direction of automatic operation, which will improve both economic and technological viability. The application of nitriding can be stretched further, e.g. to the conditioning of metal surfaces for plasma coating processes, or to obtain improved corrosion resistance. In the molten salt process compliance with environmental requirements is very important. Development is in the direction of closed systems in which spent salts, toxic wastewater, or other waste materials do not enter the environment. Similar environmental considerations apply to the gas processes.

4.2.3. Boriding

4.2.3.1. Principles

When boron diffuses into the surface zone of a ferrous workpiece, a compound layer is formed that consists of either one iron boride (Fe_2B) or two iron borides (Fe_2B in the inner, FeB in the outer layer). A diffusion zone containing boron as a solid solution is formed below the boride layer. The compound layer is strongly interlocked with the metal substrate, especially in the case of unalloyed or low-alloy steels (Fig. 24). With increasing content of alloying elements, however, this effect decreases; it is almost absent in high-alloy steels [61].

Figure 24. Schematic representation of boride layers

The two iron borides forming the compound layer ("boride layer") have different properties. The boron-rich rhombic FeB is harder and more brittle than the tetragonal Fe_2B with its lower boron content. Single-phase Fe_2B layers have much better properties than dual-phase layers. Different layer types are shown in Figure 25; those of types E and F are preferred in industrial practice. This cannot always be realized, especially with thick layers, and type D layers then must be accepted [62].

Figure 25. Types of iron boride layers (adapted from [62]) a) FeB; b) Fe_2B; c) Diffusion zone

The Vickers hardness values of the boride layer cited in literature vary between 1500 and 2300 [61]. Excellent wear properties are of higher importance, especially with respect to abrasive wear. Good results are also reported for high-speed wear and combined wear and corrosion [61].

Boron dissolved in the diffusion zone produces a considerable increase in hardenability. Since heat treatment can only be carried out after boriding, the higher hardenability results in improved load-bearing properties of the matrix material. Carbon is not soluble in the boride layer; it is substituted in the growing layer and enriched underneath. The increased carbon content contributes further to hardenability and load-bearing properties.

All types of ferrous materials are suitable for boriding, including sintered and cast products. Prolonged boriding of materials with high aluminum or silicon content ($> 0.5\,\%$) must be avoided because this leads to the formation of ferrite and and unsatisfactory cases (type G in Fig. 25).

The thickness of the borided compound layer can be varied between very wide limits: 20 – 30 µm layers are often used in machine manufacturing, while on molds for brick-making the layer can be up to 800 µm thick.

4.2.3.2. Boriding Methods

Boriding (boronizing) can be carried out in gaseous, liquid, and solid media. Although *boriding in gaseous media* has often been reported in the literature, no industrial application is known. Boron trihalides (e.g., BCl_3) and boron hydride (B_2H_6) have been proposed as gaseous media. The trihalides must be mixed with hydrogen or nitrogen. Diborane (B_2H_6) is extremely toxic and this has so far prevented its use [63].

Boriding in liquid media, (i.e., molten salts) has also been frequently reported [62] and is mainly employed in East European countries. The process is either electrolytical in molten borax or electroless in an inert melt of alkali metal chlorides containing boron carbide as boron source. Drawbacks including corrosion of the vessel, purity problems, and irreproducible results have prevented this method from becoming widely established.

Boriding with solid materials is performed with a mixture of boron carbide, an activator (frequently KBF_4), and a diluent (e.g., SiC, Al_2O_3, MgO) that allows adjustment of the boride potential. The parts to be treated are packed in this boriding medium, heated to 900 – 950 °C, and usually cooled in situ. If necessary, boriding can be followed by heat treatment. The powder can be replaced by an aqueous paste of similar composition; smaller amounts of boriding media are then required, and treatment of part of a workpiece is also possible. Boriding with powder can be carried out in air, but a protective gas (e.g., a mixture of 5 – 10 % hydrogen and 95 – 90 % nitrogen, or argon) is required for the paste.

Treatment time depends on the layer thickness required: for example, a boride thickness of 100 µm on a C45 steel requires 3 h at 900 °C (powder) or 2 h at 900 °C (paste). Single items and small series are treated in a chamber furnace; the pit-type furnace is also used for paste boriding. Large-scale boriding is carried out in a continuous furnace and can be almost fully automated.

Exploitation of the good properties of iron boride layers still fails in many cases due to the inadequate boriding methods. In the last few years much development work has been aimed at improving these processes, in particular the application of the plasma process to boriding. It remains to be seen whether this will be successful [64].

4.2.4. Other Thermochemical Processes

In addition to the processes described in Sections Case Hardening with Carburizing, Nitriding and Nitrocarburizing, Boriding a few other methods exist for special applications [36, 65]. They are rarely used.

Aluminizing. Diffusion of aluminum into the workpiece produces an aluminide phase which is resistant to oxidation up to 800 °C, especially if sulfur was present in the atmosphere.

Chromizing. Carbon steels are subjected to chromium diffusion to form chromium carbide cases with high wear resistance.

Siliconizing. Diffusion of silicon leads to solid solutions with high acid resistance.

Vanadizing. Diffusion of vanadium into carbon steels produces vanadium carbide cases with high abrasion resistance. Vanadizing is performed by a powder process or in molten borax with ferrovanadium (Japanese TD process) [66]. The TD process is still used to a small extent in Japan and several other countries for treating metal tools.

5. Thermal Spraying

All thermal spraying processes require a concentrated, high-energy heat source into which the coating material is fed in the form of wire, rod, or powder. The material melts and is impelled at high velocity onto the surface of the workpiece in the form of spray particles. Impact at the surface causes flattening of the liquid droplets and cooling as a result of heat transfer to the substrate. The particles then solidify and shrink. The temperature of the workpiece can be kept low during the coating process, so that even temperature-sensitive materials (e.g., low-melting light metals or plastics) can be deposited [67].

Many coating materials and methods can be used for thermally sprayed protective coatings. Research and development continually lead to new industrial applications. For the successful solution of technical problems, the complete system, including coating material, substrate material, and coating method must be considered [68]. Owing to the wide range of possibilities for combining substrate and coating material, thermal spraying processes find a large number of possible applications with increasing use in industry.

5.1. Methods of Thermal Spraying

5.1.1. Flame Spraying

The oldest thermal spraying processes employ a fuel gas – oxygen flame as heat source, which is used to spray metals and alloys and some ceramic materials. The material to be sprayed is fed into the flame where it melts, is broken down into fine particles (atomized), and sprayed onto the surface of the workpiece by the pressure of the flame and the carrier gases, sometimes using an additional atomizing gas such as compressed air (Fig. 26). Acetylene, propane, or hydrogen are used as fuel gases. The type of fuel gas determines the flame temperature, and the maximum temperature (3150 °C) is obtained with acetylene – oxygen. The kinetic energy of the combustion gases and the sprayed particles depends on the heat released during combustion and on the gas pressure.

Figure 26. Principle of flame spraying
a) Atomizing air; b) Acetylene – oxygen mixture; c) Wire feeding device; d) Sprayed coating; e) Workpiece

Metallic materials are usually sprayed in the form of powder and wire. Ceramic materials are fed into the flame as powder or as rods formed by sintering the powder.

In a special type of flame spraying technique, nickel, cobalt, or iron alloys are used in powder form. The powder is sprayed onto the workpiece in the first step and then fused with the substrate in the second step. Owing to the very good wetting properties of these alloys, an enormous increase in adhesive strength is achieved; furthermore, the coatings become virtually nonporous after the fusing stage. Fusing can be either carried out manually with an autogenous flame, by inductive heating if the coated workpieces are rotationally symmetrical, or in a vacuum furnace if large numbers of parts are to be treated [69]. Figure 27 shows an abrasion- and corrosion-resistant Ni–Cr–B–Si alloy which has been flame sprayed and fused onto a mold core for glass products in glass industry.

A further development in flame-spraying technology, available on the market since the 1980s, is high-velocity flame spraying (HVOF: high-velocity oxygen–fuel spraying). The common feature of all HVOF processes is the increased pressure of the fuel gases, which results in an enormous increase in the velocity of the sprayed particles. In contrast to the conventional

flame-spraying procedure, combustion occurs in an extended, sometimes cooled combustion zone [70]. The higher kinetic energy of the spray gases leads to higher velocities of the spray particles, producing much denser coatings with much better adhesion to the substrate.

Figure 27. Mold core for raw glass preparation in the glass industry, coated with a self-fluxing Ni–Cr–B–Si alloy

5.1.2. Electric Arc Spraying

In electric arc spraying, two electrically conducting pieces of wire are introduced at constant, controlled rate and predetermined angle into an electric arc spray pistol (Fig. 28). A voltage is applied and the arc is ignited between the two electrodes, giving a temperature of ca. 4000 °C and causing both wires to melt. An auxiliary gas jet from a nozzle atomizes the molten material, accelerates the particles, and causes them to impinge on the substrate. The controlled feed rate ensures uniform melting of the wires. If wires of different metals or wires filled with hard phases are used, so-called pseudo-alloys are formed. The term pseudo-alloy refers to alloys that are not in thermodynamic equilibrium, and is often used to denote hard phases (e.g., carbides, borides) that are embedded in a metallic matrix made by spraying cored wires.

Figure 28. Principle of electric arc spraying
a) Wire feeding devices; b) Wire guides and electrical contacts; c) Atomizing air; d) Wire tips melting in the electric arc; e) Sprayed coating; f) Workpiece

More recent developments of the electric arc spraying process are aimed at spraying in a vacuum or in an inert gas atmosphere, which would enable application of otherwise reactive metals [71].

5.1.3. Plasma Spraying

Plasma spraying is one of the most commonly used spray coating processes for producing functional coatings. The method uses a heat source consisting of an electric arc inside a nozzle. This heats an inert gas stream (mixtures of argon, helium, nitrogen, or hydrogen). The ionization and recombination reactions of the gas produce very high temperatures — as high as 20 000 K in the center of the plasma flame. The coating material, usually in powder form, is introduced into this high-energy plasma jet by means of a carrier gas (usually argon). The powder particles are melted and impelled onto the prepared substrate material (Fig. 29).

Figure 29. Principle of plasma spraying

Figure 30. Modern vacuum plasma spraying system

Several process developments are described below. They are all basically carried out as described above, and differ mainly with respect to process parameters (air, inert gas, vacuum, water), which in turn determine plasma-gun design, and were developed for particular applications or spraying materials [72, 73]. Application of the various thermal-spraying methods may depend on the coating material and the quality or performance of the sprayed coating. Ceramics (mostly oxides) are, for example, sprayed by atmospheric plasma spraying. Oxygen-sensitive materials (e.g., refractory metals or aluminum-containing materials) are sprayed under inert conditions (inert gas plasma spraying, vacuum plasma spraying). Due to the reduced pressure in the vacuum chamber the spray particles attain higher velocities, resulting in denser coatings and better adhesion.

Atmospheric Plasma Spraying (APS). This process is performed in open air. The sprayed particles can react with oxygen during their flight from plasma gun to workpiece.

Inert Plasma Spraying (IPS). Unlike the atmospheric plasma spraying process, the IPS process is performed in a chamber containing an inert atmosphere (usually argon) either at or slightly above atmospheric pressure. Furthermore, an additional inert gas jacket can be used. The inert gas prevents reaction between the plasma jet, the workpiece, or the sprayed particles and the surroundings, but it is not a substitute for vacuum plasma spraying.

Vacuum Plasma Spraying (VPS). Vacuum plasma spraying is performed to meet higher specifications with respect to density, purity, and low oxide content of the coating. Spraying is carried out in a chamber containing an inert atmosphere at reduced pressure (5 – 30 kPa) to prevent chemical reaction of the plasma jet, sprayed material, and substrate with the surrounding atmosphere. Coatings are formed with higher energy since the particles undergo less cooling or deceleration in the low-density gas. Figure 30 shows a modern vacuum plasma installation, and Figure 31 a tantalum coating produced by the vacuum plasma spraying process [74, 75].

Underwater Plasma Spraying (UPS). Underwater plasma spraying features large reductions in fume, dust, and radiation emissions, with the option of using the process in offshore drilling operations in which coating can be done below the sea surface [76]. Figure 32 shows an underwater plasma spraying installation.

Figure 31. Vacuum plasma sprayed tantalum coating for prevention of corrosion

Figure 32. Underwater plasma spraying equipment for water pressures up to 1.5 MPa

High-Power Plasma Spraying (HPPS). High-power plasma spraying is still under development; high plasma energies are obtained using a special gun configuration. Increased deposition rates of refractive coating materials are obtained.

5.1.4. High-Velocity Oxy–Fuel Spraying (HVOF)

High-velocity oxy–fuel spraying (HVOF) involves a fuel gas – oxygen combustion process. Owing to strong gas expansion the resulting flame leaves the nozzle of the spray gun at supersonic speed (up to 2100 m/s). The powder with carrier gas is usually injected axially into the gun, melted, and accelerated to velocities which are much higher than those obtained with arc, flame, or atmospheric plasma spraying (Fig. 33) [77].

Figure 33. Spray stream of a Sulzer Metco Diamond Jet Hybrid HVOF spray gun

Compared the latter processes, HVOF coatings are characterized by high adhesion to

Figure 34. HVOF sprayed tungsten carbide/cobalt coating for wear protection

Figure 35. HVOF spraying of ball valves (Source: Bandak AS, Norway)

the substrate, good cohesion between the particles, low porosity, low surface roughness, low loss of alloying elements, and low oxide content. The HVOF process is most suitable for the production of carbide-containing wear-resistant coatings (Fig. 34) [80], corrosion resistant coatings, and high-quality protective coatings against wear and corrosion. The HVOF process has many interesting potential applications (Fig. 35).

In contrast to detonation gun spraying (Praxair), high-velocity oxy – fuel flame spraying is a continuous combustion process of oxygen and a gaseous or a liquid fuel. Typically propane, propylene, natural gas, hydrogen, acetylene, or kerosene is used as fuel; flame temperatures are between 2700 and 3150 °C. Flame velocities up to 2100 m/s can be obtained, implying particle velocities exceeding 650 m/s, depending on the fuel used, system hardware, and the material (grain size, density).

Characteristic of the HVOF process are visible shock diamonds in the high-velocity gas jet. These shock diamonds are speed nodes that result from compression and expansion waves. The spacing, size, and shape of the shock diamonds are related to flame velocity. The HVOF process combines very high particle velocity with controlled particle heating. Thus, thermally activated chemical reactions (e.g., oxidation, phase transformation, evaporation of elements, etc.) can be better controlled and limited.

The process features of HVOF are leading to wide industrial use, and steady growth in this spray technology for all kinds of coating applications is expected in the future.

5.2. Properties of Thermally Sprayed Coatings

Properties of thermally sprayed coatings depend strongly on spraying parameters, which must be optimized for each type of coating material, workpiece, and for each method of operation.

Coating Structure. The molten, high-velocity sprayed particles acquire a spherical shape as they move toward the substrate. High-energy impact on the substrate produces a lamellar, finely crystalline structure, owing to the energy of the spray and thus to process parameters such as the viscosity of the sprayed material. The lamellar structure is typical of sprayed coatings, and conversion to the compact, finely crystalline structure can only be achieved by thermal post-treatment. Depending on the sprayed material, annealing is sometimes feasible but not necessary in many cases.

Porosity. Depending on coating material, subsequent treatment, and geometry of the coated workpiece, thermally sprayed coatings have a degree of porosity, which can be 5 – 10 % for low-energy methods (flame spraying) down to < 1 % in the case of high-velocity oxy – fuel flame spraying or high-energy vacuum plasma spraying. Since the pores are mostly closed, thermally sprayed coatings have low permeability above a certain thickness, and protect the substrate from the surroundings. Thermally sprayed coatings are usually 200 – 500 μm thick and inhibit penetration of liquid media. Their thickness

can, however, range from ca. 15 μm up to several millimeters (depending on the material and the spraying process).

Adhesion. The adhesive strength of thermally sprayed coatings depends on spraying parameters and on the substrate. Adhesion generally decreases with increasing coating thickness because of the resulting increase in internal stresses. Special pretreatment of the surface is required for maximum adhesion of a spray coating to the substrate. This consists of mechanical roughening with corundum (Al_2O_3), carborundum (SiC), or boron carbide (B_4C), which also cleans and activates the surface. Thermal spraying must immediately follow blasting to avoid reduction of adhesive strength owing to contamination or oxidation. In the vacuum plasma spray process, additional pretreatment can be performed under vacuum. An electric arc is installed between the plasma gun and the substrate in addition to the plasma-generating arc in the plasma gun itself. This additional arc cleans and heats the workpiece.

Coatings consisting of thermally sprayed oxides (e.g., zirconia, alumina) or mixtures of oxides with metals are not applied directly to the substrate but to a thermally sprayed base coating (e.g., nickel – aluminum, nickel – chromium, or another metal alloy).

Surface Roughness. Thermally sprayed coatings have varying degrees of roughness. In the as sprayed condition, roughness R_z is 5 – 30 μm, and after polishing it can be < 0.2 μm (R_z is the mean difference between the five highest peaks and the five lowest valleys in the sampling length).

5.3. Materials

5.3.1. Spray Coating Materials

Coating materials used in thermal spraying can be classified according to their form and composition. They can be used in the form of solid wires, rods, filled wires, powders, and other shapes. Spray coating compositions cover a large number of natural and synthetic products both inorganic and organic. Materials should be capable of being liquefied without decomposition, sublimation, oxidation, or other adverse effects; otherwise these reactions must be controlled during spraying.

Materials for thermal spraying include basically all materials which exhibit a liquid phase on melting at ambient pressure. Materials without a liquid phase, such as SiC, can be processed in combination with matrix materials. Materials are usually available as powders or wires.

Powders. Spray materials are classified (e.g., DIN 32 529) according to their chemical composition:

- Pure materials (e.g., Cr, W, Ni, Cu, Al, Mo)
- Alloys (e.g., NiCr, NiAl, steels, CuAl, CoCrW, MCrAlY)
- Metal carbides (e.g., WC, TiC, Cr_2C_3 – NiCr, WC – Co, WC – CrCo)
- Self-fluxing alloys (e.g., NiCrBSi)
- Oxides (e.g., B. Al_2O_3, TiO_2, ZrO_2, Cr_2O_3, Al_2O_3 – TiO_2, ZrO_2 – Y_2O_3)
- Organic materials

In addition, blends and composite powders of the above groups are possible.

Powder spray coating materials can be classified according to particle size or composition. Particle diameters are between ca. 5 and 180 μm, and the particle size distribution is usually narrow. Typical powder grain size distributions are, for example, 22 – 45 μm or 22 – 90 μm, depending on the material (e.g., melting behavior) and the spraying process. Furthermore, the flow behavior in powder feeding is of importance for maintaining a stable coating process. The range of powders is almost unlimited, and their uses as thermal spray materials for spray processes must therefore be optimized [79].

Every spraying process requires characterization and specification of the appropriate powder. The gas temperatures are sometimes extremely high (e.g., 20 000 – 30 000 K in plasma spraying), as are the spraying velocities in some cases. There are many possible process gases and surrounding atmospheres, so that different processes require different powder materials with regard to chemical composition, grain size, shape, and particle structure (dense, porous, etc.) in order to obtain the best coating properties.

Production. Important basic steps in powder production include sintering and melting with subsequent mechanical size reduction, sometimes with an additional mixing stage, followed by classification.

Powders are manufactured by atomization, spray drying, reaction spray drying, fluidized-bed sintering, coating of the particles, agglomeration, plasma spheroidizing, and other processes. Virtually all combinations of powdered materials can be produced; most of them consist of a single component, but homogeneous and heterogeneous multicomponent powders (composite powders) are also available.

Figure 36. Testing procedures and quality control for powders and coatings

Characterization. The powders are characterized by means of their chemical composition and purity, physical properties, and morphology. Important morphological parameters of individual particles or collectives are shape, surface properties, porosity, texture, structure, homogeneity and phases. Their knowledge enables coating properties and manufacturing methods to be compared [78].

A practical procedure for quality testing and quality assurance of powders and coatings is shown in Figure 36 [79].

Wires. Wires can be classified, for example, according to DIN 8566 (Parts 1 – 3). Typical spray materials in wire form are solid wires of unalloyed and low-alloy steels, high-alloy steels, nonferrous metals such as Al and aluminum alloys, copper and copper alloys, tin alloys, nickel and nickel alloys, zinc, and molybdenum, as well as cored wires.

Solid wires are used mainly in flame and electric arc spraying. All steels and a wide variety of nonferrous metals and alloys can be used, including some refractory metals that can be manufactured in wire form. Several tens of thousands of tonnes of wire are used worldwide in these processes.

Cored wires can be produced in the form of overlapped cored wire, but can also be hollow tubes (generally of steel or nickel-base alloys) that are filled with a single- or multicomponent powder (often iron – chromium – carbon, tungsten carbide, or chromium carbide). Cored wire electrodes are already used for welding and are becoming of increasing importance for spraying, especially electric arc spraying.

5.3.2. Substrate Materials

Basically all engineering materials are suitable as substrate materials, provided appropriate pretreatment has been carried out, i.e., steels, cast iron, titanium and titanium alloys, aluminum materials, nickel and nickel alloys, copper and cobalt base materials, but also to some extent ceramics, plastics, glass, and wood. Restrictions exist because of temperature limitations of the substrate material and bonding limitations between coating and subtrate. Coating of thermochemically treated substrates (nitrided, case-hardened, borided) leads to irreversible modifi-

cations of the thermochemical layer, depending on coating temperature.

Satisfactory adhesion bonding requires careful, technically correct surface preparation and application of the coating within the shortest possible time. Surface contaminants such as oil, grease, lubricants, and particles must be avoided or removed. Degreasing can carried out with chemical agents, by heating, ultrasonically, or by steam cleaning. Surface roughening is most commonly performed by blasting. The blast parameters and the blasting material must be adapted to the area to be coated. Other methods include electrolytic or mechanical processes. Surface roughening should be carried out shortly before spraying.

5.4. Applications

Thermal sprays have many applications for the enhancement of surface properties such as wear resistance (i.e., abrasion, adhesion, erosion, and scratching, Fig. 37), and corrosion resistance (atmospheric, moisture, and hot gases). Further properties of coatings can be thermal insulation (Fig. 38), electrical insulation, electrical conduction including superconducting coatings (Fig. 39), self-lubricating coatings, abradable coatings, diffusion barriers, surface-active coatings, biocompatible coatings (Fig. 40), ionically conducting coatings, and decorative coatings.

Figure 40. Plasma-sprayed hydroxyapatite on artificial hip joint implant for improvement of biocompatibility

Miscellaneous uses of thermal spraying include the manufacture of molds by spraying onto soluble cores, repair of worn parts (Fig. 41), recovery of products rejected because of faulty material or incorrect manufacture, and special powder treatments by means of melting and spheroidizing. Coating material and spraying process are selected according to the intended use of the coated article, its geometry and size, and the nature of the substrate and coating material.

6. Coloring

Decorative coloring of metals is no longer carried out on an industrial basis; anodized aluminum and aluminum alloys, as well as some special grades of stainless steel, are, however, exceptions. Only one important development has been made in the last few decades: the coloring of high-chromium stainless steel (mainly the DIN alloys 1.4301, X4CrNi18-10, and in special cases, 1.4512) to achieve a metallic luster even in outdoor applications. Metal coloring attained maximum popularity in the 1920s, but interest then declined, no further developments were made, and some of the old methods fell into oblivion. Another reason for the decline of this complicated technique was the fact that it could only be used by skilled craftsmen on individual items and was difficult to apply on an economic basis for mass production. Up to now chemical coloring has been used mainly in arts and crafts to achieve an antique decorative finishing on objects of copper (patina) and on brass and silver (brown to black coloration by immersion into polysulfide solutions). A special coloring method is the depletion of single alloy components from the surface by suitable chemical reactions, with simultaneous enrichment of the remaining components (also called surface enrichment); examples are the tumbaga gilding method (depletion gilding, mise en couleur) and depletion silvering [82]. For further details of coloring methods, see [83 – 97, 99] → Electrochemical and Chemical Deposition.

1. Introduction

Methacrylic acid [*79-41-4*], α-methylacrylic acid, 2-methylpropenoic acid,CH_2=C(CH_3) COOH, M_r 86.09, is a colorless, moderately volatile, corrosive liquid with a strongly acrid odor. It was first prepared in 1865 from ethyl methacrylate, in turn obtained by dehydration of ethyl α-hydroxyisobutyrate [1].

Historical Aspects. OTTO RÖHM's doctoral thesis (1901) on polymerization products of acrylic acid derivatives represented the start of interest in acrylates and methacrylates as materials of potential commercial value [2]. RÖHM reported the preparation of colorless, clear, rubbery materials that he thought could be of practical utility. He and OTTO HAAS formed a company to manufacture leather treatment enzymes in 1907. Although laboratory studies of the preparation of acrylates and methacrylates continued, it was not until the 1920s that significant effort was spent on the development of commercial processes for the monomers and derived polymers.

After World War I, RÖHM developed a route for commercial production of acrylates from ethylene cyanohydrin, in turn derived from ethylene chlorohydrin, an intermediate used in the production of gases for chemical warfare. Later, he and WALTER BAUER developed an analogous synthesis of methyl methacrylate using acetone cyanohydrin. By 1931 BAUER succeeded in producing a methyl methacrylate polymer as a clear, transparent solid that softened above 100 °C. This first "organic glass" could be worked with saws, drills, and other common tools, which suggested significant practical applications. Research on forming cast sheet from methyl methacrylate was carried out in the 1930s by both Rohm and Haas and Du Pont in the United States, by Röhm and Haas AG in Germany, and by ICI in England.

Commercial production of methyl methacrylate monomer began in Darmstadt, Germany in 1933 (two years after the commercial production of acrylates) by the original acetone cyanohydrin route. The cyanohydrin was converted to ethyl α-hydroxyisobutyrate by treatment with ethanol and dilute sulfuric acid. This was then dehydrated using P_2O_5 [3–7]. In 1934 a patent was issued to ICI for the conversion of acetone cyanohydrin to methacrylamide sulfate using concentrated sulfuric acid [8]. The methacrylamide sulfate could be hydrolyzed to methacrylic acid and esterified to form methyl methacrylate [*80-62-6*]. RÖHM then cross-licensed his technology for manufacture of cast acrylic sheet with ICI so that the more efficient ICI process could be used for producing methyl methacrylate monomer. Both ICI and Röhm and Haas AG began commercial production of methyl methacrylate using the methacrylamide sulfate route in 1937. Rohm and Haas in the United States (a branch of the company that had become independent in 1917) was unable to obtain a similar license until the mid-1940s, so they continued to use the original process for several years [2].

The methacrylamide sulfate route provided the basis for commercial production of methac-

rylic acid and methyl methacrylate until the 1983 introduction of isobutene oxidation processes, developed independently in Japan by Japan Catalytic Chemical and Mitsubishi Rayon. Although additional isobutene-based methacrylic acid capacity is anticipated in Japan, and a new ethylene-based facility is under construction by BASF in Ludwigshafen, most of the world demand for methyl methacrylate (1.4×10^6 t in 1988, 2.2×10^6 t in 1996 [75]) continues to be met via acetone cyanohydrin.

Table 1. Physical properties of methacrylic acid, methyl methacrylate, and butyl methacrylate

Property	Methacrylic acid	Methyl methacrylate	Butyl methacrylate

Most acetone cyanohydrin-based operations lead directly to methyl methacrylate monomer, which is the most important methacrylate derivative. Methacrylic acid produced by other routes also serves as a key intermediate to methyl methacrylate.

Much smaller quantities of ethyl methacrylate [*97-62-3*], *n*-butyl methacrylate [*97-88-1*], and isobutyl methacrylate [*97-86-9*], as well as higher methacrylates (e.g., lauryl methacrylate [*142-90-5*] and stearyl methacrylate [*32360-05-7*]) are manufactured by direct esterification of methacrylic acid or transesterification of methyl methacrylate. In addition to these, 2-hydroxyethyl methacrylate [*868-77-9*], 2-hydroxypropyl methacrylate [*923-26-2*], and aminoalkyl methacrylates such as 2-dimethylaminoethyl methacrylate [*2867-47-2*] are also commercially available. Methacrylamide [*79-39-0*] is offered as a specialty monomer; it can be obtained from the intermediate methacrylamide sulfate.

2. Properties

2.1. Physical Properties

The most important physical properties of methacrylic acid and its derivatives are listed in Tables 1 and 2 [3], [9–13]. Liquid – liquid equilibrium data for the methanol – water – methacrylic acid – methyl methacrylate system are available [14–16], as are key vapor – liquid equilibrium data for methacrylic acid – water [17] and related methacrylic ester systems [18], [19]. Solid – liquid equilibria for methacrylic acid – water have also been published [20], as have the physical properties of aminoalkyl methacrylates [21].

2.2. Chemical Properties

Methacrylic acid and its esters are very reactive, displaying reactions typical of both the vinyl function and the carboxylic acid or ester group. The electron-withdrawing effect of the carboxylic acid or ester group polarizes the double bond and enhances its reactivity, but this reactivity is less pronounced than in the acrylates because of the electron-donating methyl group. Thus, nucleophilic Michael and Michael-like additions to the double bond take place only with electron-rich reagents.

Addition to the Carbon – Carbon Double Bond. Addition of hydrogen cyanide, hydrogen halides, hydrogen sulfide, mercaptans, alkyl amines, alcohols, phenols, or phosphines leads to β-substituted α-methyl propionates [3], [5], [22], [23].

Table 2. Physical properties of methacrylic acid derivatives

[a] At 0.67 kPa.
[b] At 20 °C.
[c] At 25 °C.

Diels–Alder Reactions. Diels–Alder reactions occur with dienes such as butadiene and cyclopentadiene [3], [23], [24].

Reactions of the Carboxylic Acid Function. Esterification of methacrylic acid with alcohols in the presence of catalytic quantities of sulfuric or sulfonic acids provides the corresponding esters. Acid-catalyzed addition of olefins also gives esters [25].

Transesterification of methyl methacrylate is another convenient technique for the manufacture of esters. Catalysts include dialkyl tin oxides [26], sodium phenoxide [27], and zinc chloride [28]. Methanol formed during the reaction is removed as a binary azeotrope with methyl methacrylate.

Reaction of the methacrylic acid group with epoxides permits the synthesis of hydroxyethyl and hydroxypropyl methacrylates. Appropriate catalysts include anion-exchange resins [29], ferric chloride [30], and lithium salts [31].

Methacryloyl chloride [*920-46-7*] is synthesized by reaction of the acid with thionyl chloride or phosphorus trichloride. Methacrylic anhydride [*760-93-0*] is prepared by reaction of the acid with acetic anhydride.

Methacrylamide is most conveniently prepared by reaction of acetone cyanohydrin with sulfuric acid [6], [32], [33]. Crude methacrylamide sulfate prepared as described in Section 3.1 is first neutralized with ammonia, after which water is added. The resulting methacrylamide can be separated from the aqueous ammonium sulfate by solvent extraction, filtration, or as a melt. It can be purified further by recrystallization. Alternatively, methacrylamide can be prepared by reaction of methyl methacrylate with ammonia.

Methacrylonitrile [*126-98-7*] is produced by ammoxidation of isobutene. It may be converted to methyl methacrylate by a process similar to the cyanohydrin route.

Oxidation. In the absence of free radical polymerization inhibitors, air oxidation of methyl methacrylate leads to a polymeric peroxide that decomposes to formaldehyde and methyl pyruvate.

Polymerization. Methacrylic acid, its esters, and other methacrylate derivatives polymerize readily upon heating in the presence of free radical initiators (e.g., peroxides, UV light, or ionizing radiation). Because the usual phenolic inhibitors function by reaction with peroxy radicals rather than with carbon radicals, these do not interfere with initiated polymerization. However, oxygen must be excluded during the pro-

cess because it converts alkyl radicals to hydroperoxy radicals.

Poly(methyl methacrylate) is unusual among polymers in that its pyrolysis gives high yields of the monomer. Heating scrap or off-grade polymer above 300 °C gives > 80 % recovery of monomer, which can be purified by fractional distillation. For further details of methacrylate polymers, see → Polyacrylamides and Poly(Acrylic Acids), → Polymethacrylates.

3. Production

This chapter is restricted to production methods for methacrylic acid and methyl methacrylate, since the preparation of methacrylic acid derivatives is summarized in Section 2.2. Disregarding the role of C_1 molecules (methanol, carbon monoxide, formaldehyde, and hydrogen cyanide), the commercially practicable routes to methacrylic acid and methyl methacrylate utilize ethylene (C-2 route), propene or acetone (C-3 routes), and isobutene (C-4 route) as carbon sources. Economic considerations for the various processes depend upon regional raw material supplies and costs; none of the newer processes is so superior to the acetone cyanohydrin route as to warrant scrapping existing cyanohydrin-based plants. Further, no single alternative process is clearly superior in an economic sense to the others.

3.1. Methacrylic Acid and Methyl Methacrylate from Acetone Cyanohydrin

The most common approach to methacrylic acid synthesis is the hydrolysis of methacrylamide sulfate, obtained from acetone cyanohydrin [6], [7], [23]. Methyl methacrylate may be prepared directly in a similar way by adding methanol in the final reaction step.

Dry acetone and hydrogen cyanide react in the presence of a basic catalyst to give the cyanohydrin, which is then reacted with excess concentrated sulfuric acid (1.4 – 1.8 mol per mole of cyanohydrin) to form methacrylamide acid sulfate:

The sulfuric acid serves both as a specific reactant and as a solvent for the reaction, which appears to involve an α-sulfatoamide intermediate. If insufficient sulfuric acid is used, the reaction mass becomes a slurry or solid that is difficult or impossible to cool and pump. Both the sulfuric acid and the acetone cyanohydrin must be anhydrous in order to minimize hydrolysis of the sulfato derivative to α-hydroxyisobutyramide. The initial reaction is carried out continuously in a series of stirred tank reactors. Good heat transfer is required to assure removal of the heat of reaction. Thorough mixing is also necessary to avoid decomposition of the cyanohydrin to acetone and hydrogen cyanide, which can react to form byproduct acetone sulfonates and formamide sulfate. After initial reaction is completed at 80 –110 °C, the mixture is subjected to brief thermal cracking at ca. 125 – 160 °C to convert most of the α-hydroxyisobutyramide byproduct to methacrylamide sulfate, along with some acetone, carbon monoxide, and water. Total residence time at this stage of the process is about 1 h.

In a second stage, the methacrylamide sulfate stream is either hydrolyzed with excess water to give methacrylic acid and ammonium acid sulfate, or it is treated with aqueous methanol in a combined hydrolysis – esterification step to produce a mixture of methyl methacrylate and methacrylic acid:

Several modifications are possible in the hydrolysis – esterification step. For example, the methacrylamide sulfate, water, methanol, and recycle streams can be led through a series of continuous reactors at 80 – 110 °C with a 2 – 4 h residence time. The reactor effluent then passes to a stripping column where crude methyl methacrylate, water, and excess methanol are removed overhead. The waste acid ammonium

sulfate residue can be either treated with ammonia for conversion to fertilizer or burned to regenerate sulfuric acid. Crude methyl methacrylate is extracted with water to recover methanol, which is concentrated and recycled to the esterification reactor. Washed ester is then purified by further distillation. The overall yield based on acetone cyanohydrin is in the range of 80 – 90 %.

In the manufacture of methacrylic acid, methacrylamide sulfate is reacted with water under conditions similar to those used for formation of the ester. The reactor effluent separates into two phases. The upper organic layer is distilled to provide pure methacrylic acid. The lower layer is steam stripped to recover dilute aqueous methacrylic acid, which is recycled to the hydrolysis reactor. The waste acid stream is treated as in the manufacture of the ester.

In an alternative process, shown in Figure 1, the methanolysis reaction is carried out at a pressure of ca. 800 kPa in one or more reactors (d) operated at 100 – 150 °C. The reactor effluent is separated into two layers (e) while still under pressure. The lower layer is steam stripped (g) to recover methacrylic acid for recycle to the esterification reactor (d), and acid waste is treated as described previously. The upper layer is passed to a distillation column (f) where light ends (primarily dimethyl ether) are removed. The bottoms from this column are washed with aqueous ammonia (h) to recover methanol and methacrylic acid for recycle to the esterification reactor. The crude, washed methyl methacrylate is then dehydrated in a downstream distillation column (i) and distilled in a product column (j) to provide pure methyl methacrylate.

A sulfuric acid regeneration plant is usually operated in conjunction with the methyl methacrylate plant, because approximately 1.6 kg of sulfuric acid is required to produce each kilogram of methyl methacrylate. The presence of a regeneration facility avoids the need to dispose of large quantities of ammonium sulfate contaminated with organic material.

One of the driving forces for development of the alternative routes discussed in Sections 3.2, 3.3, 3.4 has been the desire to eliminate the need for sulfuric acid regeneration. An additional concern is the hazard associated with transporting hydrogen cyanide, which is not always generated at the methacrylate plant site. On the other hand, both acetone (from phenol manufacture) and hydrogen cyanide (from acrylonitrile manufacture) have the economic advantage of being themselves industrial byproducts.

Asahi Chemical manufactures methyl methacrylate by the sulfuric acid hydrolysis of methacrylonitrile, using a plant originally designed for the acetone cyanohydrin process. The requisite methacrylonitrile is obtained by ammoxidation of isobutene, avoiding the need for hydrogen cyanide.

3.2. Methacrylic Acid from Isobutene

In recent years many companies have investigated the manufacture of methacrylic acid by two-stage catalytic oxidation of isobutene or *tert*-butanol. Nihon Methacryl Monomer (a joint venture of Sumitomo and Nippon Shokubai) and Mitsubishi Rayon have both constructed commercial plants using this technology.

In the first stage of the process [4], isobutene is oxidized to methacrolein (→Acrolein and Methacrolein, Chap. 3.2.), and in a second stage the methacrolein is oxidized to methacrylic acid:

$$CH_2{=}\underset{\underset{CH_3}{|}}{CH}{-}CH_3 + O_2 \longrightarrow CH_2{=}\underset{\underset{CH_3}{|}}{CH}{-}CHO + H_2O$$

$$CH_2{=}\underset{\underset{CH_3}{|}}{CH}{-}CHO + 1/2\,O_2 \rightarrow CH_2{=}\underset{\underset{CH_3}{|}}{CH}{-}COOH$$

A published account of process and catalyst developments [34], [35] contrasts methacrylic acid production from isobutene with a similar process for preparing acrylic acid from propene. Selectivity of the second-stage catalysts is best at modest conversions (65 – 85 %). In the Sumitomo–Nippon Shokubai process shown in Figure 2, the first-stage reactor is operated at high conversion, and its effluent passes directly to the second oxidation reactor [36]. Conversion in the second stage is kept low in order to ensure good catalyst selectivity and increase catalyst life. Unreacted methacrolein from the second-stage reactor effluent is separated and recycled. The overall yield of methacrylic acid from isobutene is about 65 – 70 %. Typical catalysts for the first stage are multicomponent metal oxides containing bismuth, molybdenum, and several other metals to promote activity and

Figure 1. Production of methyl methacrylate from acetone cyanohydrin

modify selectivity [37–41]. Second-stage catalysts are based on phosphomolybdic acid, but they usually contain an alkali metal to control the acidity. Other elements such as copper and vanadium may also be present [42–46].

Reactor effluent from the second-stage oxidation passes to a quencher (b) where crude aqueous methacrylic acid is obtained. The gaseous effluent from the quencher is passed to an absorber (c) where the unreacted methacrolein is absorbed, usually in aqueous carboxylic acid. Absorber off-gases are sent to a combustion unit (d) before being discharged to the atmosphere. A portion of the incinerated gases may be recycled to the first-stage reactor to provide inert gas diluent for the feed. The methacrolein absorbate is transferred to a methacrolein recovery tower (e) from which methacrolein is recycled to the second-stage oxidation reactor; recovered absorbent solution is returned to the absorber.

The crude, aqueous methacrylic acid is sent to a solvent extraction unit (f) for methacrylic acid recovery. Next, a solvent recovery/dehydration tower (h) affords crude methacrylic acid as a bottoms product. The overhead organic solvent layer is recycled to the extraction step, whereas the overhead aqueous layer is combined with extractor raffinate and sent to a solvent stripping tower (g) before being subjected to wastewater treatment.

Dry, crude methacrylic acid from the extract stripper can be further purified if methacrylic acid is the desired end product, or it can be sent directly to an esterification reactor (i) where catalyst and methanol are added for conversion to methyl methacrylate. Crude ester is extracted with water (j) to recover excess methanol, which is removed by distillation (k) and recycled to the esterification reactor. The washed, crude ester is sent to a light ends stripper (l) for removal of light byproducts (e.g., methyl acetate) and then distilled (m) to provide pure methyl methacrylate. The bottoms from the final distillation column are recycled to the first extraction step with the exception of a small bleed for removal of inhibitor residues.

Plants based on the C-4 route were introduced in Japan by Nippon Shokubai in 1982 and by Mitsubishi Rayon in 1983 [35]. A joint venture plant operated by Sumitomo and Nippon Shokubai came on stream in 1984. Mitsui Toatsu and Kyowa Gas have also announced plans to construct a plant of this type. Several firms, including Nippon Kayaku, Mitsui Toatsu, Rohm and Haas, and Oxirane (a joint venture of Halcon SD and ARCO) have carried out extensive re-

Figure 2. Production of methyl methacrylate from isobutene

search on the isobutene process. In 1987 ARCO acquired exclusive worldwide rights to Halcon SD technology using C4-feedstocks [47].

Halcon has proposed a variation of this process that commences with dehydrogenation of isobutane [48], [49].

3.3. Methacrylic Acid from Isobutyric Acid

Acid-catalyzed carbonylation of propene to isobutyric acid, followed by oxidative dehydrogenation, presents still another route to methacrylic acid. In this case the starting material is propene itself rather than the oxydized derivative acetone, as in the acetone cyanohydrin route. Although the propene – isobutyric acid – methacrylic acid route is not currently in commercial use, several major methyl methacrylate manufacturers have research efforts aimed at its commercialization.

In the first stage of the process, propene, carbon monoxide, and water are reacted in the presence of a strong acid catalyst to produce isobutyric acid. Sulfuric acid, hydrogen fluoride, and boron fluoride have all been reported to be effective catalysts [50–53]. Patents to Röhm [54] and Ashland Oil [55] describe variations that involve preliminary preparation of isobutyroyl fluoride, which is then hydrolyzed to isobutyric acid. Alternatively, isobutyric acid may be synthesized directly by including carefully controlled amounts of water in the carbonylation step:

Hydrogen fluoride (which acts as both solvent and catalyst), carbon monoxide, and propene (14 – 40 : 1.5 : 1) are reacted in the presence of a slight stoichiometric deficiency of water relative to propene to generate isobutyric acid. Reaction conditions are included in the patent literature; these range from about 30 °C at 20 MPa to 120 °C at 14 MPa. Depending upon the temperature and pressure, residence time during the carbonylation step varies from about

5 to 30 min. Reactor effluent is passed to staged flash tanks, in the first of which excess carbon monoxide can be recovered for recycle to the carbonylation reactor. The second tank permits removal of inert gases, which can be passed to the atmosphere after scrubbing with caustic solution to remove any hydrogen fluoride or isopropyl fluoride. The bulk of the hydrogen fluoride is separated overhead in a distillation tower for recycle to the carbonylation reactor. The bottoms from this tower pass to a hydrolysis stripper where any remaining fluorine-containing materials are reacted with water; hydrogen fluoride is stripped off for recycle. A final distillation step provides isobutyric acid overhead for feed to the second part of the process. Bottoms from this distillation contain small amounts of C_7 and C_{10} carboxylic acids resulting from multiple condensations of propene prior to reaction with carbon monoxide. The overall selectivity with respect to propene is reported to be 95 – 97 %. The preceding steps must be carried out in a facility carefully designed to prevent fugitive fluoride emissions.

In the second stage of the process, isobutyric acid, steam, and air are passed over a fixed-bed catalyst [56–60] in a multitubular reactor, causing oxidative dehydrogenation to methacrylic acid. The reactor effluent is sent to a quench tower from which an aqueous methacrylic acid stream is obtained. This part of the process is similar to the methacrolein oxidation step in the C-4 process described in Section 3.2. In addition to carbon monoxide and carbon dioxide, which are incinerated with other noncondensable gases, the crude methacrylic acid stream contains acetone and acetic acid as byproducts. If desired, and with proper choice of quench tower conditions, the acetone can be directed to the incinerator along with the noncondensables.

If methacrylic acid is to be isolated, the crude product may be extracted into a solvent and dehydrated in a distillation tower. Isobutyric and acetic acids are then separated by distillation as light ends prior to final distillation of the methacrylic acid. The distillative separation of isobutyric acid from methacrylic acid is very difficult; normal boiling points of the two materials are 155 and 162 °C, respectively.

Catalysts for the oxidative dehydrogenation of isobutyric acid to methacrylic acid are of two general types. The first series, often referred to as Mo – P – V mixed oxide catalysts, were developed by Mitsubishi Chemical Industries [57], Röhm [58], [59], and others, and they are similar in composition to catalysts used in the oxidation of methacrolein. Most are phosphomolybdic acid derivatives, usually with some replacement of molybdenum by vanadium or tungsten. The better catalysts frequently contain at least some copper, and they are partially neutralized by cesium, rubidium, or potassium. Some catalysts are reported to achieve conversions of 99.8 % with selectivities above 74 % [59].

A second type of catalyst has been intensively studied by Ashland Oil [61]. These include iron phosphate materials and give selectivities of about 84 – 85 % at conversions in the 85 – 95 % range. Such catalysts are used at about 400 °C, in contrast to ca. 300 °C for the phosphomolybdate catalysts. Iron phosphate catalysts require high levels of steam in the reactor feed for optimum selectivity and life.

According to patents issued to Röhm [62], crude reactor product from the oxidative dehydrogenation step can be sent directly to the esterification reactor, which constitutes the starting point for the third section of the process. In this case, the product methyl methacrylate must be separated from methyl acetate and methyl isobutyrate. Separation of methyl isobutyrate from methyl methacrylate is difficult because its boiling point (92 °C) is close to that of methyl methacrylate (101 °C). The esterification step is similar to that described in Section 3.2 for the C-4 process.

Norsolor has an exclusive European license to the Ashland Oil technology, which Norsolor has further developed in a pilot plant at St. Avold (France) [63]. Röhm has developed its own process for this route in a pilot plant at Darmstadt [64].

An alternative process involves the hydroformylation of propene to give isobutyraldehyde, followed by oxidation of the aldehyde to isobutyric acid [65].

3.4. Methacrylic Acid From Ethylene

Other routes to methacrylic acid include the condensation of formaldehyde with propionic acid to generate methacrylic acid and the condensation of formaldehyde with propanal to give methacrolein [66–69].

BASF has developed such a process based on ethylene, synthesis gas, and formaldehyde. A plant with a production capacity of 40 000 t/a came on stream at Ludwigshafen in 1990 [70], [76].

Ethylene is first hydroformylated to give propanal, which is then condensed with formaldehyde to produce methacrolein. Catalytic air oxidation of methacrolein to methacrylic acid completes the synthesis, a step that is common to the C-2 and C-4 routes:

$$CH_2{=}CH_2 + CO + H_2 \longrightarrow CH_3CH_2CHO$$

$$CH_3CH_2CHO + HCHO \longrightarrow CH_2{=}\underset{\underset{CH_3}{|}}{C}HCHO + H_2O$$

An alternative process would entail oxidation of propanal to propionic acid, condensation of which with formaldehyde would give methacrylic acid directly.

4. Quality Specifications

Glacial methacrylic acid is typically available in a purity exceeding 99.4 % (analysis by GC and HPLC). Water (ca. 0.1 – 0.2 wt %) is the primary contaminant. Traces of α-hydroxyisobutyrate may also be present. The monomethyl ether of hydroquinone (MEHQ) at 100 – 250 ppm is used as an inhibitor during storage and transportation. Commercial methyl methacrylate is typically 99.9 % pure, with traces of acidity (< 0.003 %) and water (< 0.05 %). The storage and transportation inhibitor for the methyl ester is generally 10 – 50 ppm of MEHQ or 25 – 60 ppm of hydroquinine, though other phenolic inhibitors can also be used. Phenothiazine is an excellent inhibitor in this case because it has both anaerobic and aerobic activity. Nevertheless, it is not commonly used in products intended as polymer intermediates.

5. Storage and Transportation

The heat of polymerization of methacrylic acid is -56.5 kJ/mol; corresponding values for the methyl, ethyl, and *n*-butyl esters are -57.7, -57.7, and -56.5 kJ/mol, respectively. These highly exothermic reactions may occur with violence if the monomers are not properly inhibited against the formation of free radicals. Appropriate inhibitor levels have been established with great care by the manufacturers, resulting in excellent stability to polymerization under normal conditions of storage and transportation. Once stabilized, methacrylic acid and its derivatives can be handled as flammable liquids. The flammability limits of methyl methacrylate in air at 20 °C are 2.12 – 12.5 vol%.

The effectiveness of typical phenolic inhibitors depends upon the presence of oxygen. For this reason, methacrylic monomers should always be stored in contact with a vapor space whose oxygen concentration is 5 – 21 % (dry air) in order to maintain a sufficient level of dissolved oxygen [11].

Like many other unsaturated organic materials, methacrylic monomers react slowly with oxygen to give peroxides, hydroperoxides, and other compounds. Formation of such materials is greatly retarded by polymerization inhibitors and accelerated by increased temperature, but deterioration of product quality and stability must be anticipated upon extended storage (several months to a year). Storage temperatures should generally be kept below 25 °C.

Methacrylic acid has a relatively high freezing point (15.8 °C), and inhibitors tend to partition strongly into the liquid phase during freezing. Hence, thawing of frozen methacrylic acid can give initial melts that are significantly depleted in inhibitor. If such a liquid is heated, thermal initiation can give rise to violent polymerization. Care should thus be taken to avoid the possibility of freezing. If freezing takes place, thawing should preferably be conducted at 25 °C, and never above 40 °C. Furthermore, material should never be removed until melting is complete and the liquid has been thoroughly mixed to restore uniform inhibitor levels.

The preferred construction material for methacrylic acid storage vessels is type 316 stainless steel. Although less corrosion-resistant materials are suitable for methacrylate esters, stainless steel should be considered for these as well, because rust or iron salts can induce free radical decomposition of the peroxides that accumulate on long storage.

Transport Regulations. Methacrylic acid is classified as a flammable and corrosive liquid. Transport is governed by the IMDG-Code no.

D 8257, class B; UN-no. 2531; RID/ADR class 8, number 31 c; CFR 49 : 172.102 corrosive material.

6. Uses

Methacrylic acid and methacrylate esters are used to prepare a wide range of polymers [→ Polyacrylamides and Poly(Acrylic Acids), → Polymethacrylates]. Poly(methyl methacrylate) is the primary polymer in this category, and it provides water-clear, tough plastics that are used in sheet form in glazing, signs, displays, and lighting panels. Automotive lighting lenses and similar products can be prepared from molding pellets. Methyl methacrylate incorporated into copolymers forms the basis for durable coatings and inks. Higher methacrylate polymers are useful in the manufacture of oil additives, solventless inks and coatings, and binders for xerography. Salts of poly(methacrylic acid) can serve as the basis for water-soluble thickeners and detergent additives.

7. Economic Aspects

The cost of methyl methacrylate varied widely among the three major economic regions of the world in 1988. Japanese prices in early 1988 approached \$ 1.76/kg (80 cents/lb), the price in Europe was ca. \$ 1.43 – 1.48/kg (65 – 67 cents/lb), while the United States price was \$ 1.17 – 1.23/kg (53 – 56 cents/lb). World capacity is of the order of 1.4×10^6 t/a. The principal manufacturers and their existing capacities are listed in Table 3 [71], [72]. Projected capacities after completion of expansions and probable retirements of facilities are also given. The normal growth rate in demand is 3 – 3.5 %/a. Announced expansions by BASF in Germany, by Rohm and Haas and Du Pont in the United States, and by Sumitomo – NSKK and Mitsui Toatsu – Kyowa Gas Chemical in Japan are expected to satisfy demand into the 1990s.

8. Toxicology and Occupational Health

Acrylic monomers have been the subject of animal toxicity studies covering a variety of exposure routes. Larger esters are found to be less well-absorbed and less toxic than smaller esters. Generally speaking, methacrylates are less toxic than acrylates. Relevant data are provided in Table 4 [11], [73], [74].

With respect to acute toxicity, single exposures to acrylic monomers by the oral or dermal route appear to be slightly to moderately dangerous. This conclusion is based on lethality studies with rats and rabbits. The mucous membranes of the eyes, nose, and throat are particularly sensitive to irritation. Acrylic monomers can produce eye and skin irritation ranging from slight to corrosive depending upon the monomer.

Full eye protection should always be worn during handling of methacrylate monomers. Prolonged exposure to either liquid or vapor can result in permanent eye damage and possibly blindness. Overexposure to vapors causes nose and throat irritation, as well as dizziness or drowsiness (solvent narcosis) and possibly central nervous system depression. Thus, respiratory protection and proper ventilation are required in cases of exposure to high vapor concentrations.

Swallowing methacrylate monomers may lead to severe irritation of the mouth, throat, esophagus, and stomach, causing discomfort, vomiting, diarrhea, dizziness, and possibly collapse. Direct contact with the monomers causes skin redness and irritation ranging from slight to severe, perhaps including corrosion. Methacrylic acid is more corrosive than its esters. Because the monomers irritate and may be absorbed through the skin, gloves and protective clothing are required when handling these materials.

Repeated exposure to methacrylate monomers can produce allergic dermatitis (or skin sensitization), which results in rash, itching, or swelling. After one or more exposures to a given monomer, allergic responses sometimes are produced by single exposures to the same or other acrylic monomers.

Repeated exposure of animals to extremely high (near lethal) concentrations of monomer vapor has produced inflammation of the respiratory tract and degenerative changes in the liver, kidneys, and heart muscle. Liver and kidney changes have also been observed during prolonged oral exposure. These effects were the result of concentrations far above the threshold

Table 3. Worldwide methyl methacrylate capacity

Company	Location	Capacity, 10^3 t/a		Process ∗
		Current	Projected	
United States

Table 4. Toxicity data for methacrylic monomers

	Methyl methacrylate	Butyl methacrylates	Methyl acrylic acid
Oral LD_{50} (rat), g/kg	7.9 – 9.4	20.3	1 – 2
Dermal LD_{50} (rabbit), g/kg	> 9.4	10.2	> 2
Skin irritation (rabbit)	slight to moderate	moderate	corrosive
Eye irritation (rabbit)	slight to moderate	slight	corrosive
Inhalation LC_{50} (rat), ppm	7093	1720	> 1300
OSHA PEL, ppm [74]			20
TLV – TWA (1989 – 1990) [73]			
mg/m^3	410∗		70
ppm	100∗		20
Odor threshold, ppm	0.083	0.016	10

∗ These also represent the MAK values.

levels known to cause irritation. No such effects have been reported for humans, who presumably would leave a highly contaminated area rather than tolerate the irritation.

Current TLV – TWA and OSHA PEL values appear in Material Safety Data Sheets provided by methacrylate manufacturers upon request. Values for 1989 are also listed in Table 4 [73], [74].

Protection required for the safe handling of methacrylic acid and its esters includes chemical-resistant gloves and clothing, splash-proof goggles, and good ventilation of the workplace. Contact with these materials should be followed by flushing with copious amounts of water. Medical attention should be sought if symptoms appear.

1. Introduction

Methane [*74-82-8*], CH_4, M_r 16.03, *mp* − 182 °C, *bp* − 162 °C, is a colorless gas that burns with a blue flame. Some physical properties of methane are as follows:

Specific heat capacity at − 100 °C	5.34 J g^{-1} K^{-1}
Density at − 170 °C	0.4362 g/cm^3
Viscosity at − 170 °C	0.142 mPa · s
Surface tension at − 170 °C	15.8 mN/m
Latent heat of fusion	0.942 kJ/mol
Latent heat of evaporation at	8.185 kJ/mol
$Kp_{101.3\,kPa}$	≈ 0.510 kJ/g
Minimum calorific value	50.0 kJ/g
Heat of formation	− 74.897 kJ/mol
Entropy	186.31 J K^{-1}mol^{-1}
Free energy of formation	50.83 kJ/mol
Critical values:	
Temperature	− 82.5 °C
Pressure	4.67 MPa
Density	0.162 g/cm^3
Minimum auto-ignition temperature (MAIT) (VDE 0173)	535 °C
MAIT varies according to method of determination	between 601 and 748 °C
Flame velocity	43.4 cm/s
Flame velocity varies according to method of determination	between 34 and 44 cm/s
Explosion limits in air at 20 °C and 0.1 MPa	
lower	5.0 vol %
upper	15.0 vol %
Compressibility factor	0.299
Solubility in water	
at 20 °C, 101.3 kPa CH_4	33.8 mL/L
at 35 °C, 101.3 kPa CH_4	25.4 mL/L
Henry's constant in water	
at 20 °C	1.45 × 10^{-3} mol/L atm
at 35 °C	1.005 × 10^{-3} mol/L atm

Methane is more soluble in organic solvents than in water. Ethanol dissolves 32 cm^3 methane per 100 cm^3 at 0 °C. Diethylether dissolves 106.6 cm^3 methane per 100 cm^3 at 0 °C. Methane forms a hydrate, $CH_4 \cdot 6\,H_2O$, which has a decomposition temperature at 0.1 MPa of − 29 °C, a critical decomposition temperature of 21.5 °C and a dissociation pressure at 0 °C of 2.6 MPa.

Naturally occurring methane is essentially of biological origin. Methane has been produced in nature by the dismutation of organic matter since the origin of life on earth. Fossil methane is described in → Natural Gas. Methane is formed in the production of gas from coal or hydrocarbons (see → Gas Production) and in refining of oil (→ Oil Refining).

All organic matter, left to itself, will ultimately be transformed (dismutated) by microorganisms under anaerobiosis into carbon dioxide and methane.

Indeed, nature obtains energy through redox reactions. The ultimate reducing step is the reduction of carbon to methane, and the ultimate oxidizing step, the oxidation of carbon to carbon dioxide [1].

The biological process by which organic matter is transformed into methane and carbon dioxide is called methanogenesis. When this biological process is housed in a reactor to create a technological process, it is known as biomethanation. The term anaerobic digestion is also widely used, but may lead to confusion with other anaerobic digestion processes that do not involve gen-

eration of methane. The mixture of carbon dioxide and methane is called biogas, a registered trade name of the Institute of Gas Technology in Chicago, United States, but widely used by the public.

Biomethanation is of interest, firstly because the biogas produced is an energy vector of economic interest, and secondly because the raw material or feedstock is often waste, which can hence be treated by the process [2], [3]. Wastewaters can be treated by biomethanation to yield acceptable effluents for receiving surface waters, and sludges can be treated to yield stabilized end products with useful agricultural properties [4–6].

2. Physical and Chemical Properties of Biogas

Biogas contains variable proportions of carbon dioxide and methane, usually somewhat more of the latter than of the former. Biogas is usually saturated with water and also contains minor and trace compounds, the major of which is hydrogen sulfide (see Table 1). The composition of biogas depends firstly upon the composition of the feedstock from which it originates and secondly upon the physicochemical equilibrium reached or maintained in the digesting mixed liquor [7].

Table 1. Composition of biogas

Component	Content, vol %
Methane	52 – 95
Carbon dioxide	9 – 45
Hydrogen sulfide	0.001 – 2
Hydrogen	0.01 – 2
Nitrogen	0.1 – 4
Oxygen	0.02 – 6.5
Argon	0.001
Carbon monoxide	0.001 – 2
Ammonia	trace
Organics	trace

Biogas has many of the chemical and physical properties of its parent constituent methane. Of course, the presence of carbon dioxide changes the chemical and physical properties. As an example, Table 2 shows the dependence of the density of biogas upon composition.

Table 2. Densities of methane and biogas of various composition

Methane content, %	50	60	80	90	100
Gas density relative to air	1.040	0.942	0.745	0.652	0.555

Whereas methane has a minimum calorific value of 50.0 MJ/kg (35.9 MJ/m^3), upgraded biogas containing 90 vol % methane has a minimum calorific value of 45.0 MJ/kg (32.3 MJ/m^3). Mean biogas, with 60 vol % methane, has a minimum calorific value of 30.0 MJ/kg or 21.5 MJ/m^3.

The flammability of biogas is shown in Figure 1. The chemical and physical properties of biogas are collected in [8].

Figure 1. Flammability limits of biogas
The flammability limits of biogas are included in the dashed triangle. Point ○ refers to a gas mixture of 24 % carbon dioxide, 68 % air, and 8 % methane

3. Biological Methanogenesis

Microorganisms transform organic matter into methane by the process depicted in Figure 2. The process consists basically of two steps, linked by interspecies hydrogen transfer. In the first step, fermentative bacteria dissolve, depolymerize, and metabolize organic matter into acetate, inorganic carbon (e.g., CO_2, HCO_3^-, and CO_3^{2-}), and hydrogen. In the second step, methanogenic microbial species dismutate acetate into methane

and inorganic carbon, and reduce inorganic carbon with hydrogen to produce methane:

$$CH_3COO^- + H_2O \rightleftharpoons CH_4 + HCO_3^-$$
$$\Delta G^{0\prime} = -31.0\,\text{kJ/formular conversion}$$

$$4\,H_2 + HCO_3^- + H^+ \rightleftharpoons CH_4 + 3\,H_2O$$
$$\Delta G^{0\prime} = -135.6\,\text{kJ/formular conversion}$$

Figure 2. Flowsheet for biological methanogenesis

Whenever the first fermentative step produces organic metabolites other than acetate, for example, anions of short-chain carboxylic acids such as propionate and butyrate and alcohols such as ethanol or butanol, a link process, mediated by obligate hydrogen-producing acetogenic bacteria, transforms these metabolites into acetate and hydrogen. For thermodynamic reasons, the latter transformation can only take place at very low partial pressures of hydrogen. In stable, efficient methanogenic processes, the hydrogen partial pressure ranges between 1 and 10 Pa. An abrupt 2 – 4-fold increase in hydrogen partial pressure or an hydrogen partial pressure above 20 Pa is indicative of misfunctioning of the process. The increased partial pressure of hydrogen results in accumulation of intermediate organic metabolites, and in the vast majority of cases, the pH drops below 6 and methane generation stops.

The methanogenic microorganisms are archaebacteria [9], which are probably the oldest known living organisms. Other microorganisms interfere with hydrogen scavenging. Acetogenic bacteria can reduce inorganic carbon with hydrogen to produce acetate, and sulfate-reducing bacteria reduce sulfate with hydrogen to form hydrogen sulfide:

$$H^+ + SO_4^{2-} + 4\,H_2 \rightleftharpoons HS^- + 4\,H_2O$$
$$\Delta G^{0\prime} = -152\,\text{kJ/formular conversion}$$

More recently, it has been suspected that some hydrogen-scavenging microorganisms are also able to reduce organic molecules containing nitrogen, sulfur, or halogens. The methanogenic consortium appears in this way to play a fundamental role in detoxication and, hence, in the environmental protection of humans.

Figure 3. Schematics of the main designs of biomethanation reactors

4. Technological Biomethanation

The biological process of methanogenesis was discovered by VOLTA in 1776, but it was over

100 years later that this biological process was first exploited technologically. MOURAS in France (1881), SCOTT-MONCRIEFF (1890) and CAMERON (1892) in the United Kingdom, HOUSTON (1892) and TALBOT (1894) in the United States, and IMHOFF (1905) in the Federal Republic of Germany, were the first to apply methanogenesis to reduce the organic matter content of sewage sludge and wastewater [10].

There are three generations of reactors for biomethanation [11]. The first generation includes the completely mixed reactor, run either in batch or in continuous mode (Fig. 3 A and B). In the batch system, the feedstock is introduced at once and left in the reactor until the reaction is terminated. In the continuous mode, the feedstock is continuously loaded into the reactor and the effluent continuously removed (e.g., by overflow) at the same flow rate. Batch systems are mainly used for more solid feedstocks, whereas the continuous mode is better adapted to more fluid feedstocks.

Figure 4. Egg-shaped reactor for the two-stage biomethanation of municipal sludge in the continuous mode at Schijnpoort, Antwerp, Belgium (courtesy of Biotim, Antwerp, Belgium)

As an example, in the European Community, there were in 1988 about 27 400 aerobic municipal wastewater treatment plants. Sewage sludge produced by these plants can be evaluated at 9×10^6 t/a of dry matter. The biomethanation of two-thirds of this represents a potential production of biogas equivalent to 1.5×10^6 t of oil per year [12]. Figure 4 shows a typical egg-shaped anaerobic digester for municipal sewage sludge.

As another example, animal manure has been frequently biomethanized in reactors run in the continuous mode to produce biogas as an energy source and stabilized manure as a fertilizer and soil conditioner. In the European Community in 1989, about 470 biogas plants on farms were in existence. In rural areas of developing countries, reactors of 5 – 20 m^3 capacity, run in the continuous mode on animal waste, mainly cattle dung, exist in very large numbers for producing energy and fertilizer at the family level. More than three million such digesters are in use in China, more than one million in India, and several thousand in other countries.

An interesting example of biomethanation in the batch mode is given by landfills (Fig. 3 C) [13]. Very large amounts of domestic solid waste are disposed of worldwide as huge landfills (several hundreds to several millions of tonnes each). Large amounts of biogas (several thousands of cubic meters per hour) are produced by natural fermentation in these landfills over long periods of time (10 – 20 years). The landfill gas escapes to the atmosphere, presenting a fire and explosion hazard, a source of damage to nearby vegetation, and a substantial contribution to the greenhouse effect. It can be made cost effective to extract and utilize the biogas produced in landfills. This environmental biotechnological industry started in the United States in the early 1970s, mainly in California, and spread in Europe, mainly in the Federal Republic of Germany and the United Kingdom. In the European Community, 107 landfills where biogas is exploited were identified in 1988, and this number is growing.

However, it quickly appeared that the first generation of anaerobic reactors, operating either in the batch mode or in the continuous mode without recycle (known in the United States as once-through mode), present severe limitations of performance for a number of reasons, the most important of which is the lowering in the concentration of active microorganisms (often referred to as active biomass) that arises because active biomass is lost when the effluent is removed.

A second generation of reactors for biomethanation was developed, in which the active biomass is either trapped in the anaerobic reactor or is recycled to it after sedimentation (Fig. 3 D and E). Sedimentation occurs either in a separate decanter or in a built-in decanter. The latter type was developed as early 1970 under the trade name Clarigester. In the Clarigester, the liquid waste enters at the bottom of

the reactor and flows upwards through a bed of active biomass. It then overflows into a built-in decanter, in which the active biomass sediments and returns to the reactor, while the effluent escapes from the top of the digester.

Figure 5. Tower anaerobic filter for the two-step anaerobic treatment of starch-containing wastewater
The towers are 22 m high and are filled with 16 layers of polyurethane foam matrices of 1.2 m thickness
By courtesy of Biotim, Antwerp, Belgium

It was found that the active biomass, under conditions that are still not well understood, organizes itself as heavy granules. This led to the upflow anaerobic sludge blanket (UASB) system (Fig. 3F), which was developed since 1970 by Lettinga in the Netherlands [14] and is a milestone in the application of biomethanation to the anaerobic digestion of agro-industrial and other wastewaters.

In a variant, the active biomass is either trapped within a polymeric foam, notably polyurethane, or adsorbed on an inert carrier (e.g., baked clay or plastic rings) (Fig. 3 G). The latter system carries the generic name anaerobic filter. The active biomass is referred to as a fixed film. When the inert carrier, usually large particles or matrices, is mainly immobile in the reactor, the system is known as a stationary bed. When the inert carrier, usually small particles such as sand or active carbon, expands and becomes mobile in the reactor, the system is termed a fluidized bed. Figure 5 shows a typical full-scale anaerobic filter for the anaerobic treatment of starch-containing wastewaters.

The third generation of biomethanation systems includes combinations of the former designs. For example, because the biological process consists of two steps, it has been found advantageous in some cases to optimize each biological step in a separate reactor. This is referred to as a two-step system and was first introduced in 1970 [15]. Other two-stage systems have an active biomethanation in the first stage and a finishing biomethanation stage with effluent clarification in the second stage. These are often applied to the biomethanation of sewage sludge and this explains, as can be seen in Figure 4, why egg-shaped digesters usually operate in pairs.

5. Feedstocks for Biomethanation [16]

Feedstocks for biomethanation include energy crops and organic wastes. Energy crops are plants grown mainly for producing energy. They include terrestrial and aquatic plants; the latter have been more intensively investigated. Typical aquatic energy crops are water hyacinths (*Eichhornia*) in soft waters and marine algae such as kelps (*Macrocystis*).

Organic wastes have become classical feedstocks for biomethanation [17]. They can be classified as domestic, industrial, or agricultural, according to their origin [18]. Feedstocks of domestic origin include municipal wastewaters, sewage sludges, and municipal solid wastes. Municipal wastewaters are progressively being investigated for anaerobic treatment. Sewage sludges have been stabilized by biomethanation for over 100 years. Domestic solid wastes are routinely biomethanized in landfills but are also being considered as feedstocks for biomethanation in engineered reactors.

Industrial wastes as feedstocks for biomethanation presently include mainly food wastes, originating from breweries, distilleries, fermentation industries, processing of coffee, fat, meat, milk, shellfish, fruit and vegetables, olive and palm oil mills, slaughterhouses, and starch and sugar refineries. They also include an increasing proportion of other agro-industrial wastes

such as those originating from pulp and paper mills and the textile and tanning industries. Even pharmaceutical, (petro)chemical and coal gasification wastes are presently being considered for biomethanation. Industrial wastes range in physical state from wastewaters through sludges to solid material. Agro-industrial wastewaters are now routinely treated anaerobically. More than one hundred mature, economic, and reliable full-scale plants have been built worldwide [19].

Agricultural wastes as feedstocks for biomethanation consist mainly of animal wastes [20]. Whereas all kinds of animal manure are suitable for biomethanation, cattle and pig manure are the main targets, not only for energy and methane production but also for pollution control. Very large scale biogas plants, have been developed in Denmark, Italy and The Netherlands, among others, that are intended for a group of farms appear more reliable and profitable than smaller biogas plants on single farms. Agricultural and animal wastes for biomethanation are of increased interest for developing countries.

In the European Community, the potential for biogas from domestic waste is equivalent to 10×10^6 t of oil; the potential for biogas from agricultural waste is equivalent to 23×10^6 t of oil and the potential for biogas from energy crops could be $9-57\times10^6$ t of oil [19]. In the European Community, there already exists a total biomethanation reactor volume of 6×10^5 m^3 producing 0.49×10^6 m^3 of methane per day (equivalent to 0.15×10^6 t of oil per year).

6. Process and Environmental Parameters for Stable, Efficient Biomethanation

The process parameters characteristic for running a biomethanation system are the space loading rate, the concentration of the feedstock, and the mean residence time. The space loading rate is the mass of feedstock (as total dry matter, organic matter, or COD) per unit digester working volume per day. The ratio of the concentration to the space loading rate gives the mean residence time (excluding any accumulation factor arising from trapping of solid feedstock by sedimentation in imperfectly mixed reactors), usually in days. The state parameters characteristic of the performance of a biomethanation system are the rate of gas production and the residual concentration of dry organic matter in the effluent or its residual COD. The yield is calculated either by the ratio of produced methane to added or consumed feedstock, or from the residual concentration in the effluent. Stability of the methanogenic process is an important aspect of performance. The process parameters related to stability are the concentration of volatile fatty acids (indicative of the equilibrium within the methanogenic microbial consortium), the hydrogen partial pressure (see Chap. 3), and the alkalinity or bicarbonate concentration (linked to the acidification potential of the feedstock).

Degradation of 1 kg of COD produces stoichiometrically 350 L (at STP) or 250 g of methane. One kilogram of average organic matter corresponds to 1 – 1.4 kg of COD, depending on its mean oxidation state.

In completely mixed systems conducted in the continuous mode without recycle, practical space loading rates remain below 3 kg per cubic meter per day. The mean retention time must remain above 14 d, and this severely limits the concentration of the feedstock. Gas production rates range between 0.5 and 1.5 (sometimes up to 3) volumes of gas per unit digester volume per day.

In systems with trapped active biomass, ca. 10 – 20 and, in exceptional cases, up to 40 kg of active biomass can be housed in 1 m^3 of digester volume. The food to microorganism ratio is the potential amount of feedstock transformed per day per kilogram of active biomass. Acceptable values of food to microorganism ratio range around 1, sometimes higher. Space loading rates in these systems with trapped biomass can thus be increased up to 10 – 40 kg per cubic meter per day. Mean residence times can be lowered to one day or less with favorable feedstocks, i.e., those for which the fermentative step is fast, such as sugar-containing wastewaters. Gas production rates can increase to 4 – 10 volumes of gas per unit reactor volume per day.

Yields vary from 30 % to over 95 %. Animal manure usually gives low yields: 30 % for cattle manure and up to 45 % for pig manure. Sugar-containing wastewaters can be 95 % digestible (at least in terms of BOD). Planning of biogas plants has been reviewed in [21], [22].

Several factors govern the process of methanogenesis in the technology of biomethanation, namely temperature, pH, anaerobiosis, carbon to nitrogen ratio, micronutrients, toxic elements in the feedstock, and inoculum.

There are two temperature ranges for optimum biomethanation, the mesophilic range at ca. 35 °C and the thermophilic range at ca. 60 °C. Thermophilic biomethanation results in faster gas production and higher yields, but the process is often less stable. The requirement for process temperatures above ambient temperature means that methane digesters need to be well insulated and that external process heat is often required. Part of the biogas produced (ca. 30 %) is usually used for this purpose. Between 20 and 30 °C, both methane production and methanogenic microbial growth are still possible, but at lower rates and yields. Below 20 °C, methane production remains possible, but microbial growth becomes progressively slower.

Biological methanogenesis occurs at pH 6.8 – 8.2. A pH below 6.5 inhibits the second, methanogenic step of the biological process but not the first, fermentative step. Under these conditions, the metabolization of organic carbon yields organic anions, for which the only possible pairing cation is the hydrogen ion. As a result of the accumulation of acid anions, the pH of the digesting mixed liquor drops. Bicarbonate alkalinity limits this pH drop by acting as a buffer and through formation of carbon dioxide.

$$H_3O^+ + HCO_3^- \overset{-H_2O}{\rightleftharpoons} H_2CO_3 \rightleftharpoons H_2O + CO_2\,(sol) \overset{-H_2O}{\rightleftharpoons} CO_2\,(g)$$

This explains in part why biogas contains carbon dioxide besides methane. The buffering action of nitrogenous compounds is discussed below.

Methanogenesis is a strictly anaerobic process. Some species of the methanogenic consortium are very sensitive to oxygen. However, the methanogenic consortium also includes facultative aerobic – anaerobic microbial species. Therefore, the methanogenic fermentation mixture can easily overcome an occasional limited exposure to air. The fermentative first step of the biological process of methanogenesis occurs at low redox potentials (E^0 well below 0 mV). The methanogenic second step occurs at even lower redox potentials (E^0 a couple of hundred mV below).

The carbon to nitrogen ratio is an important parameter for efficient biomethanation. First, nitrogen is required for cell growth. Average cell yield is 15 g of dry cells per 100 g of transformed feedstock in anaerobiosis. The nitrogen requirement is 1.7 g per 100 g feedstock. Second, the mineralization of organic nitrogen yields ammonia and ammonium ions. Ammonia produced in this way exerts a buffering capacity complementing that of bicarbonate and is therefore useful in pH control. Optimum mass ratios of carbon to nitrogen given in the literature range between 16 and 19. Shortage of nitrogen in a feedstock can best be overcome by mixing it with another feedstock richer in nitrogen.

Micronutrients are essential for efficient biomethanation. Metal ions seem to be necessary for methanogenic archaebacteria, notably up to 50 mM Na^+ and 2 – 100 mM Fe(II). Cobalt (50 nM) and nickel (100 nM) are essential trace elements for the reduction of carbon dioxide to methane by hydrogen.

Toxic compounds are often present in feedstocks at concentrations that inhibit biomethanation. For example, ammonia is inhibitory at concentrations of 1.7 g/L (as NH_4^+/NH_3). These concentrations are often encountered in pig manure. Heavy metal cations inhibit biological methanogenesis. However, most heavy metal cations form insoluble sulfides. Appropriate amounts of sulfate in the feedstock, a substrate for sulfate-reducing bacteria, normal hydrogen-scavenging members of the methanogenic consortium, help to overcome this potential inhibitory effect. This phenomenon has been conceived as a possible environmental biotechnology for the removal of heavy metals by concentration of insoluble compounds.

Many organic compounds are toxic to methanogenic microorganisms; an example is chloroform. Antibiotics such as monensin are used in animal feed to prevent methanogenesis in the rumen. Hence, animal manure may contain inhibitory concentrations of these antibiotics.

However, the methanogenic microbial consortium exhibits astonishing acclimation to toxic compounds [23]. Furthermore, the methanogenic microbial consortium includes detoxifying microbial species.

The methanogenic microbial consortium is more widely spread in nature than previously thought. However, due to the slow growth rate of several members of the consortium, and the even slower process of stabilization of the equilibrium between species in the consortium, the use of a large inoculum shortens the start-up period. This is especially true for solid feedstocks such as those in landfills. Methanogenic microorganisms do not seem to migrate rapidly over long distances (ca. 1 m). Appropriate and well mixed inocula may well prove to be essential for enhanced landfill gas generation.

When methanogenic microorganisms with adhesion properties are required for 2-d or 3-d generation methane reactors, it has proved more successful to use as inoculum the active flocculent sludge from aerobic wastewater treatment, as harvested at the bottom of the secondary decanter, rather than sludge obtained from the anaerobic stabilization reactor.

The use of specialized and acclimated inocula for given toxic or recalcitrant feedstocks can help reduce the start-up and acclimation periods. Enzymatic preparations have been claimed to be able to enhance biomethanation; however, no full proof for this exists. In the case of septic tanks, the enhancement was found to be due to inorganic contaminants which acted as inert carriers for microbial adhesion.

7. Environmental Impact of Biomethanation

Methanogenesis in nature and biomethanation by humans have a double impact on the environment. On the one hand, waste treatment has a positive impact, but biogas may have a negative impact.

Biomethanation is an environmental technology that can be applied at various scales from the family-size in rural tropical areas through farm-size in developed countries to industrial scale. In some cases, this environmental biotechnology can be made cost effective and give rise to an economic market.

As only the carbon of the organic matter is transformed to methane, all other elements remain in the digested effluent. The digested effluent of biomethanation is stabilized; that is, it undergoes further transformation only very slowly. Hence, it can be applied to soil without damage to plants.

Because it contains nitrogen, phosphorous and potassium, digested effluent has a fertilizer value. When the effluent is liquid, it can be used for "fertirrigation". When biomethanation proceeds from agricultural waste, it allows recycling of the valuable mineral elements. The digested effluent also contains lignocellulosic material, which is only poorly degraded because lignin is resistant to anaerobic degradation. This fibrous residue has excellent soil conditioning properties.

Biogas is flammable and explosive when appropriately mixed with air (see Fig. 1) and put in contact with an ignition source. Biogas generated in landfills migrates by diffusion and along pressure gradients. Biogas migrating in the root zones of plants creates asphyxia which can result ultimately in the death of vegetation. Biogas migrating in confined areas, such as the basements of buildings, creates explosion hazards. Several cases have been reported, some with fatal consequences for people. Nevertheless, landfill gas can easily be monitored and its migration is easily controlled. Furthermore, the gas can be profitably extracted, so that in the long term the concept of landfilling is not endangered.

It has been estimated that 1.2×10^9 t of methane are emitted annually into the atmosphere [24], resulting in a concentration of 1.4 ppm in air. Ten percent of this is fossil methane; 10 % originates from animal wastes and human sewage; 5 % from the anaerobic fermentation of human domestic wastes; and 5 % from biomass burning, notably from forest fires. Natural ecosystems, including notably termites, which account for 10 – 20 %, contribute to the remaining methane in the atmosphere. Methane has been calculated to have a mean residence time in the atmosphere of 3.3 years. Atmospheric methane concentration has doubled within a few centuries. Another doubling is expected 2050s. The atmospheric warming associated with the increase in methane concentration in the atmosphere during the last decade has been calculated to amount to about 38 % of the effect of carbon dioxide [25].

8. Storage, Pretreatment, Upgrading and Uses of Biogas

Biogas can be stored in low pressure gasholders, in medium-pressure tanks (1 – 100 m^3; 1 – 2 MPa), in high-pressure gas cylinders (30 – 50 L; 20 MPa), or as liquefied gas below the critical temperature of methane (− 82.5 °C). Low-pressure gasholders can be divided into wet and dry gasholders. Wet gasholders consist of floating rigid bells, usually of steel, with a capacity of 50 – 5000 m^3. Dry gasholders are made of rubber or plastics and store from 1 – 1000 m^3 of biogas.

Biogas must usually be pretreated before enduse. In any case, its 5 % water vapor content must be condensed. Condensed water is a major source of corrosion. Hydrogen sulfide whenever present in too large amounts must be removed. Chemical absorption of hydrogen sulfide onto iron oxides is one of the possible treatments. Whenever necessary, trace elements are removed by adsorption on active charcoal.

Biogas sometimes needs to be upgraded to methane, to be used as a substitute or a complement of natural gas, as town gas, or as a motor fuel. Carbon dioxide is removed by absorption in water or by molecular sieves. The pressure swing method, consisting of absorption under high pressure and release under low pressure periods, is often used. Selective membranes for the separation of methane and carbon dioxide are also widely used.

Biogas can be used to generate light using glowing mantles, a common practice in rural developing areas, and for heating and cooking; atmospheric and forced draft burners need to be adapted.

Biogas does not belong to any of the three families of combustible gases [8] and is thus not interchangeable with any gas belonging to these three families. The gas jet of burners must be enlarged and the pressure of the gas supply lowered. The air supply must be slightly increased. In some cases, modifications of the burner design is necessary.

Biogas can be used for mechanical power generation. Spark ignition, internal combustion, Otto engines require the addition of a gas carburettor to provide a stoichiometric air – biogas mixture to the combustion chambers. Compression ignition, internal combustion, diesel engines usually work with biogas on the dual-fuel engine basis. The latter engines use a homogeneous biogas – air mixture compressed below its autoignition conditions and ignited by the injection of pilot diesel fuel. Engine modifications concern air and biogas supply and diesel injection. The properties of biogas as a motor fuel are described in further detail in → Automotive Fuels.

Electrical power can be generated using a stationary biogas engine connected to a generator. Combined heat and power generation is very interesting in the case of biogas. The recovery of waste heat, as occurs for example in total energy modules (TOTEM), can provide the process heat necessary for controlling the temperature of the digester.

Whenever high rates of methane production are available, for example from landfills, gas turbines can be used.

9. Analysis

Biogas volumetric production rates are easily measured using conventional domestic gas flowmeters. Biogas composition is best measured by gas chromatography using Porapak Q as an inert support in a first column, a molecular sieve in a second column, and a catharometer for detection. Gases appear in the order hydrogen, oxygen, nitrogen, carbon dioxide, and methane. The ratio of carbon dioxide to methane in biogas can be estimated approximatively with a very simple device. A known volume of biogas is pumped into a small portable vessel, and the pressure is adjusted to an arbitrary 100 % value. Carbon dioxide is then absorbed in sodium hydroxide solution; the ratio is calculated from the pressure drop.

The COD or the content of organic dry matter are the most common parameters for assessing feedstock and effluent. Individual short-chain carboxylic acids are best determined by gas chromatography with Chromosorb W 100 as inert support, acidified Carbowax as stationary phase and a flame ionisation detector. The total concentration of acids can be determined by steam distillation followed by titration. Alkalinity is another important process parameter; it is usually determined by acid titration, removal of

carbon dioxide and back titration [26]. Low partial pressures of hydrogen (1 – 1000 ppm) can easily be determined by polarography.

10. Biogas in Developing Countries

[27], [28]

In rural areas of developing countries, biogas from domestic and agricultural wastes is a potential substitute for fuel wood. Most designs are based on the Chinese and Indian designs. A hybrid family digester designed by the German Technical Cooperation Agency (Gesellschaft für technische Zusammenarbeit, GTZ) is depicted in Figure 6. The optimum volume for a family digester is ca. 8 – 10 m^3. Between 10 and 15 kg of dry organic waste will produce about 3 m^3 of biogas containing 55 % of methane. This daily feedstock requirement corresponds to 60 – 80 kg fresh dung originating from six to eight head of cattle, half time in stabulation. The daily produced biogas suffices for 7.5 h use of a cooking burner, or alternatively 6 h of a cooking burner and 3 h of a biogas-fueled glowing-mantle lamp, or 3 h of a cooking burner, 3 h of lighting and 24 h of a 80 L biogas-fueled refrigerator, or 2 h of a 1 kW engine [29]. The replacement of fuel wood by biogas in developing countries will however require one or more generations.

11. Economic Aspects

Environmental biotechnology, for example wastewater treatment, is usually considered as a necessary cost, without any profit. Biomethanation should not follow this way of thinking.

A thousand methane digesters have been constructed in Europe for an average investment per cubic meter of working volume ranging from ca. € 300 for biogas plants on farms to ca. € 410 for industrial biogas plants. Methane digesters produce biogas which has an energy value and can hence be used as a substitute for conventional energy and can be valued for the substituted energy. In Denmark, the public authorities add a financial incentive equivalent to the energy taxes on top of that value. As an average, on the basis of the present energy prices, the value of biogas covers 20 % of the financial costs of biomethanation. The digested effluent, mainly when it is solid material has a potential value equivalent to that of compost, that is, ca. 40 € per ton. However, when the feedstock is municipal solid waste, marketing of the compost-like end-product is still proving difficult. The digested effluent can also be priced at the value of substituted energy. Preparing one ton of compost requires 6200 MJ. A digested effluent containing nitrogen, phosphorous and potassium can be valued for these elements. In a fertilizer, nitrogen values 18.5 MJ, potassium, 3.35 MJ, and phosphorous, 2.31 MJ.

Figure 6. German – Chinese methane digester for a rural tropical family
a) Feedstock inlet; b) Digestion chamber; c) Floating dome gasholder; d) Overflow outlet; e) Gas outlet; f) Water trap

Whenever the feedstock is a waste, it has a cost to be paid by its producer as municipal taxes for domestic solid waste disposal or as pollution taxes for wastewater treatment. Pollution-tax abbatments for agro-industries that treat their wastewaters by biomethanation contribute 80 % of the financial costs of an anaerobic treatment plant. When the biogas produced can be used in the plant (e.g., to generate process heat), this waste treatment technology ends with a no-profit, no-cost balance in these industries. In developing countries, it now appears possible to build family-size digesters for a price acceptable to the buyer, for example the price of a head of cattle in Burundi or the price of a bicycle in China, with a minimum federal financial incentive, corresponding to the macro-economic savings (deforestation, hard currency).

1. Introduction

Methanol [*67-56-1*], CH_3OH, M_r 32.042, also termed methyl alcohol or carbinol, is one of the most important chemical raw materials. Worldwide production capacity in 1989 was ca. 21×10^6 t/a. About 85 % of the methanol produced is used in the chemical industry as a starting material or solvent for synthesis. The remainder is used in the fuel and energy sector; this use is increasing. In 1993 world wide production capacity was 22.4×10^6t/a.

Historical Aspects. Methanol was first obtained in 1661 by Sir Robert Boyle through the rectification of crude wood vinegar over milk of lime. He named the new compound *adiaphorus spiritus lignorum*. Justus von Liebig (1803 – 1873) and J. B. A. Dumas (1800 – 1884) independently determined the composition of methanol. The term "methyl" was introduced into chemistry in 1835 on the basis of their work.

From ca. 1830 – 1923, "wood alcohol", obtained by the dry distillation of wood, remained the only important source of methanol. As early as 1913, A. Mittasch and coworkers at BASF successfully produced organic compounds containing oxygen, including methanol, from carbon monoxide and hydrogen in the presence of iron oxide catalysts during developmental work on the synthesis of ammonia. The decisive step in the large-scale industrial production of methanol was made by M. Pier and coworkers in the early 1920s with the development of a sulfur-resistant zinc oxide – chromium oxide catalyst. By the end of 1923 the process had been converted from the developmental to the production stage at the BASF Leuna Works.

Processes based on the above work were performed at high pressure (25 – 35 MPa) and 320 – 450 °C. They dictated the industrial pro-

duction of methanol for more than 40 years. In the 1960s, however, ICI developed a route for methanol synthesis in which sulfur-free synthesis gas containing a high proportion of carbon dioxide was reacted on highly selective copper oxide catalysts. This and other related low-pressure processes are characterized by fairly mild reaction conditions (5 – 10 MPa, 200 – 300 °C). Methanol can now be produced much more economically worldwide by these low-pressure methods.

2. Physical Properties

Methanol is a colorless, neutral, polar liquid that is miscible with water, alcohols, esters, and most other organic solvents [1], [2]; it is only slightly soluble in fat and oil. Because of its polarity, methanol dissolves many inorganic substances, particularly salts.

The most important physical data for methanol follow [3], [4]:

Density (101.3 kPa), liquid	
at 0 °C	0.8100 g/cm^3
at 25 °C	0.78664 g/cm^3
at 50 °C	0.7637 g/cm^3
Critical pressure	8.097 MPa
Critical temperature	239.49 °C
Critical density	0.2715 g/cm^3
Critical volume	117.9 cm^3/mol
Critical compressibility	0.224
mp	− 97.68 °C
Heat of fusion (101.3 kPa)	100.3 kJ/kg
Triple-point temperature	− 97.56 °C
Triple-point pressure	0.10768 Pa
bp (101.3 kPa)	64.70 °C
Heat of vaporization (101.3 kPa)	1128.8 kJ/kg
Standard enthalpy of formation	
at 25 °C (101.3 kPa), gas	− 200.94 kJ/mol
at 25 °C (101.3 kPa), liquid	− 238.91 kJ/mol
Free enthalpy of formation	
at 25 °C (101.3 kPa), gas	− 162.24 kJ/mol
at 25 °C (101.3 kPa), liquid	− 166.64 kJ/mol
Standard entropy	
at 25 °C (101.3 kPa), gas	239.88 J mol^{-1} K^{-1}
at 25 °C (101.3 kPa), liquid	127.27 J mol^{-1} K^{-1}
Specific heat, c_P	
at 25 °C (101.3 kPa), gas	44.06 J mol^{-1} K^{-1}
at 25 °C (101.3 kPa), liquid	81.08 J mol^{-1} K^{-1}
Viscosity (25 °C)	
Liquid	0.5513 mPa · s
Vapor	9.68 × 10^{-3} mPa · s
Thermal conductivity (25 °C)	
Liquid	190.16 mW m^{-1} K^{-1}
Vapor	14.07 mW m^{-1} K^{-1}
Electrical conductivity (25 °C)	(2 – 7) × 10^{-9} Ω^{-1} cm^{-1}
Dielectric constant (25 °C)	32.65
Dipole moment	5.6706 × 10^{-30} C · m
Refractive index n_D^{20}	1.32840
n_D^{25}	1.32652
Surface tension in air (25 °C)	22.10 mN/m
Flash point (DIN 51 755)	6.5 °C
Open vessel	15.6 °C
Closed vessel	12.2 °C
Explosion limits in air	5.5 – 44 vol %
Ignition temperature (DIN 51 794)	470 °C

The temperature dependence of selected physical properties is given in [5]; thermodynamic data can be found in [6] and the heat capacity and enthalpy of the liquid in [7].

The vapor pressure of methanol is determined according to [8] by a Wagner equation of the form

$$\ln p = 8.999 + \frac{512.64}{T}\left(-8.63571q + 1.17982q^{3/2} - 2.4790q^{5/2} - 1.024q^5\right)$$

where $q = 1 - T/512.64$; T is the absolute temperature, and p the pressure in kilopascals. Further vapor pressure correlation data in the temperature range 206 – 512 K are given in [9], and critical data in [10]. A selection of binary azeotropes is shown in Table 1, and a comprehensive summary is given in [11].

Viscosity data of the pure components have been published in [5], [12], [13] for the liquid phase, and in [13] for the vapor. The viscosity and density of aqueous methanol solutions at 25 °C are shown in Table 2. Temperature-dependent densities of the binary mixture are given in [15] and [16]; viscosities are documented in [15] and [17]. The pressure dependence of viscosity has been measured [18], and isothermal compressibilities, coefficients of thermal expansion, partial molar volumes, and excess factors accounting for the difference between real and ideal behavior can be found in [19]. Information on the liquid – solid phase equilibrium in the methanol – water system is given in [20].

Data on the thermal conductivity of liquid methanol appear in [21]; the electrical conductivity of the pure liquid and dielectric properties are given in [22] and [23], respectively. Safety aspects have also been discussed [24], [25].

Table 1. Binary azeotropic mixtures of methanol [11]

Component	*bp* of component, °C	*bp* of azeotrope, °C	Methanol content of azeotrope, wt %

0.9140	0.825	800.1	0.660

3. Chemical Properties

Methanol is the simplest aliphatic alcohol. As a typical representative of this class of substances, its reactivity is determined by the functional hydroxyl group [26–28]. Reactions of methanol take place via cleavage of the C−O or O−H bond and are characterized by substitution of the −H or −OH group (→ Alcohols, Aliphatic, Chap. 2.2.) [29]. In contrast to higher aliphatic alcohols, however, β-elimination with the formation of a multiple bond cannot occur.

Important industrial reactions of methanol include the following (Fig. 1):

1) Dehydrogenation and oxidative dehydrogenation
2) Carbonylation
3) Esterification with organic or inorganic acids and acid derivatives
4) Etherification
5) Addition to unsaturated bonds
6) Replacement of hydroxyl groups

4. Production

4.1. Principles

4.1.1. Thermodynamics

The formation of methanol from synthesis gas can be described by the following equilibrium reactions:

Figure 1. Industrially important reactions of methanol

$$CO + 2\,H_2 \rightleftharpoons CH_3OH \quad \Delta H_{300\,K} = -90.77\,\text{kJ/mol} \tag{1}$$

$$CO_2 + 3\,H_2 \rightleftharpoons CH_3OH + H_2O \quad \Delta H_{300\,K} = -49.16\,\text{kJ/mol} \tag{2}$$

Reaction enthalpies are determined from the standard enthalpies of the reactants and products [30]. Both reactions are exothermic and accompanied by a decrease in volume. Methanol formation is thus favored by increasing pressure and decreasing temperature, the maximum conversion being determined by the equilibrium composition.

In addition to the two methanol-forming reactions, the endothermic reaction of carbon dioxide and hydrogen (Eq. 3, the reverse water-gas shift reaction) must also be taken into account:

$$CO_2 + H_2 \rightleftharpoons CO + H_2O \quad \Delta H_{300\,K} = 41.21\,\text{kJ/mol} \tag{3}$$

For the sake of simplicity, Equations (1) and (3) can be discussed as independent reaction pathways. The conversion of carbon dioxide to methanol (2) is then the overall result of Equations (1) and (3), and the equilibrium constant K_2 can be described as $K_2 = K_1 \cdot K_3$. When the nonideal behavior of gases is taken into account, the equilibrium constants are determined as follows:

$$K_1 = \left[\frac{f_{CH_3OH}}{f_{CO}\, f_{H_2}^2}\right] = \left[\frac{\varphi_{CH_3OH}}{\varphi_{CO}\, \varphi_{H_2}^2}\right]\left[\frac{p_{CH_3OH}}{p_{CO}\, p_{H_2}^2}\right] = K_{\varphi 1} \cdot K_{p1} \tag{4}$$

$$K_3 = \left[\frac{f_{CO}\, f_{H_2O}}{f_{CO_2}\, f_{H_2}}\right] = \left[\frac{\varphi_{CO}\, \varphi_{H_2O}}{\varphi_{CO_2}\, \varphi_{H_2}}\right]\left[\frac{p_{CO}\, p_{H_2O}}{p_{CO_2}\, p_{H_2}}\right] = K_{\varphi 3} \cdot K_{p3} \tag{5}$$

where f_i is the fugacity, φ_i the fugacity coefficient, and p_i the partial pressure of the i-th component.

A number of numerical formulations exist for calculating the temperature-dependent equilibrium constants K_1 [31–38] and K_3 [36–39]; their results differ widely [40]. The binomial formulations of Cherednichenko (Eq. 6) [34] and Bisset (Eq. 7) [39] are examples:

$$K_1 = 9.740 \times 10^{-5} \exp\left[21.225 + \frac{9143.6}{T} - 7.492 \ln T + 4.076 \times 10^{-3} T - 7.161 \times 10^{-8} T^2\right] \tag{6}$$

$$K_3 = \exp\left[13.148 - \frac{5639.5}{T} - 1.077 \ln T - 5.44 \times 10^{-4} T + 1.125 \times 10^{-7} T^2 + \frac{49170}{T^2}\right] \tag{7}$$

The fugacity coefficients can be determined according to [41] by assuming ideal solubility for the individual pure components, or they can be calculated from suitable equations of state [42], [43].

The carbon monoxide and carbon dioxide conversions up to attainment of equilibrium are shown as a function of pressure and temperature in Table 3 [35]. A synthesis gas formed by

Table 3. Temperature and pressure dependence of the carbon monoxide and carbon dioxide equilibrium conversions [35]

Temperature,	CO conversion *			CO_2 conversion		
°C	5 MPa	10 MPa	30 MPa	5 MPa	10 MPa	30 MPa
200	96.3	99.0	99.9	28.6	83.0	99.5
250	73.0	90.6	99.0	14.4	45.1	92.4
300	25.4	60.7	92.8	14.1	22.3	71.0
350	− 2.3	16.7	71.91	9.8	23.1	50.0
400	− 12.8	− 7.3	34.1	27.7	29.3	41.0

* Negative sign denotes CO formation via Equation (3) [44]: $CO_2 + H_2 \rightleftharpoons CO + H_2O$.

steam reforming was chosen as the starting gas (15 vol % CO, 8 vol % CO_2, 74 vol % H_2, and 3 vol % CH_4). Equations (6) and (7) were used to establish temperature dependence, and the fugacity coefficients were determined according to the Soave – Redlich – Kwong equation. The negative sign for the carbon monoxide conversion denotes carbon monoxide formation by back-conversion [44].

4.1.2. Kinetics and Mechanism

The formation of methanol, as a typical heterogeneously catalyzed reaction, can be described by an absorption – desorption mechanism (Langmuir – Hinshelwood or Eley – Rideal). The nature of the active centers in the copper – zinc oxide – alumina catalysts used under industrial conditions is still a subject of discussion (see Chap. 5). The active species in low-pressure methanol synthesis may be a solution of copper(I) ions in the zinc oxide phase [45]. On the other hand, evidence can be found that copper(0) also catalyzes methanol formation. The feed gas composition (particularly the proportions of CO_2 and H_2O) also plays an important role in determining the activity and selectivity of catalysts in methanol production. Investigations have shown that various routes must exist for the formation of methanol via carbon monoxide or carbon dioxide, and that different active centers in the catalyst are involved [46–50].

According to [51], alumina exists in an X-ray amorphous form. The proposed functions of alumina in copper – zinc oxide – alumina catalysts include:

1) prevention of sintering of the fine copper particles by the formation of zinc spinel;
2) stabilization of the highly disperse copper – zinc oxide catalyst system; and
3) formation of surface defects by the incorporation of alumina clusters in the copper lattice [46], [51].

Which effect prevails in methanol synthesis is still not clear. However, alumina has an important function as a structural promoter in copper – zinc oxide catalysts by improving their mechanical stability and long-term activity.

Some kinetic investigations have concentrated on the role of carbon dioxide in methanol synthesis, which aroused a great deal of controversy during the 1980s [40], [46], [52–54]. Until the beginning of the 1980s, mechanistic considerations were based almost exclusively on the hydrogenation of carbon monoxide to methanol (Eq. 1, see 4.1.1) [55–59]. The increased yield achieved by adding carbon dioxide was ascribed to the displacement of the reverse water-gas shift equilibrium (Eq. 3). In addition, carbon dioxide was assumed to influence the oxidation state of the active centers in the catalyst [45].

In contrast, Kagan et al. [60] proposed that methanol was formed solely according to Equation (2) from carbon dioxide. Recent experiments with isotope-labeled reactants show that both reaction pathways (Eqs. 1 and 2) are possible [61], [62]. Similar results were obtained in other studies [63–65]. However, according to [62], formation via carbon dioxide predominates under conditions of large-scale industrial methanol synthesis.

4.1.3. Byproducts

Commercially available $Cu-ZnO-Al_2O_3$ catalysts for the low-pressure synthesis of methanol permit production of the desired product with high selectivity, typically above 99 % referred to the added CO_x.

The following impurities are important for the large-scale industrial process:

1) Higher alcohols formed by catalysis with traces of alkali [66–68]

$$n\,CO + 2n\,H_2 \rightleftharpoons C_nH_{2n+1}OH + (n-1)\,H_2O$$

2) Hydrocarbons and waxes formed by catalysis with traces of iron, cobalt, and nickel according to the Fischer–Tropsch process [67, 69, 70]

$$CO + 3\,H_2 \rightleftharpoons CH_4 + H_2O$$

$$CO_2 + 4\,H_2 \rightleftharpoons CH_4 + 2\,H_2O$$

$$n\,CO + (2n-1)\,H_2 \rightleftharpoons C_nH_{2n+2} + n\,H_2O$$

3) Esters [68], [70], [71]

$$(CH_2O)_{ads} + (RCHO)_{ads} \rightleftharpoons CH_3COOR$$

4) Dimethyl ether [70], [72]

$$2\,CO + 4\,H_2 \overset{Al_2O_3}{\rightleftharpoons} CH_3-O-CH_3 + H_2O$$

5) Ketones [73]

$$RCH_2CH_2OH \rightleftharpoons RCH_2CHO + H_2$$

$$2\,RCH_2CHO \rightleftharpoons RCH_2COCHRCH_3 + O_{ads}$$

The formation of most byproducts from synthesis gas, particularly C_2^+ species, is thermodynamically favored over methanol synthesis. Because methanol constitutes the main product, however, reactions yielding impurities are controlled kinetically rather than thermodynamically [40]. In addition to catalyst constituents and feed gas composition, the residence time at the catalyst [68], as well as the temperature [69], [70], mainly determine the extent of byproduct formation: an increase in these parameters raises the proportion of byproducts. A detailed discussion of individual byproduct classes is given in [40].

4.2. Catalysts

4.2.1. Catalysts for High-Pressure Synthesis

The first industrial production of methanol from synthesis gas by the high-pressure process employed a catalyst system consisting of zinc oxide and chromium oxide. This catalyst, which was used at 25–35 MPa and 300–450 °C, was highly stable to the sulfur and chlorine compounds present in synthesis gas [44], [54], [74], [75].

Production of methanol with zinc oxide–chromium oxide catalysts by the high-pressure process is no longer economical. A new generation of copper-containing catalysts with higher activity and better selectivity is now used. The last methanol plant based on the high-pressure process closed in the mid-1980s. For a detailed discussion of high-pressure methanol catalysts, see [74].

4.2.2. Catalysts for Low-Pressure Synthesis

Well before the industrial realization of low-pressure methanol synthesis by ICI in the 1960s, copper-containing catalysts were known to be substantially more active and selective than zinc oxide–chromium oxide catalysts. Copper oxide–zinc oxide catalysts and their use in the production of methanol were described by BASF in the early 1920s [76], [77]. These catalysts were employed at 15 MPa and 300 °C.

Their industrial use was prevented, however, by a serious disadvantage: impurities such as hydrogen sulfide and chlorine compounds in synthesis gas rapidly deactivated the catalysts. Nevertheless, the copper-containing catalyst systems proved to be the most promising candidates for producing methanol industrially at lower temperature and pressure. A series of publications on this topic appeared between 1925 and 1955 [74], [78], [79]. Investigations of copper catalysts continue to this day [53].

A low-pressure catalyst for methanol synthesis was first used industrially in the process developed by ICI in 1966. This copper oxide–zinc oxide catalyst was thermally stabilized with alumina. It was used to convert extremely pure (i.e., largely free of sulfur and chlorine compounds, $H_2S < 0.1$ ppm) synthesis gas to methanol [80]. Because this copper catalyst was extremely active, methanol synthesis could be carried out at

220 – 230 °C and 5 MPa. Premature aging due to sintering of copper was thereby avoided. The high selectivity of the new catalyst gave a methanol purity > 99.5 %. The formation of byproducts (e.g., dimethyl ether, higher alcohols, carbonyl compounds, and methane) associated with the old high-pressure catalyst, was drastically reduced or, in the case of methane, completely eliminated.

All currently used low-pressure catalysts contain copper oxide and zinc oxide with one or more stabilizing additives (Table 4). Alumina, chromium oxide, or mixed oxides of zinc and aluminum have proved suitable for this purpose [81], [82].

4.2.3. Production of Low-Pressure Catalysts

Catalysts now used in low-pressure methanol synthesis plants and based on copper – zinc – aluminum (or chromium) are obtained as metal hydroxycarbonates or nitrates by coprecipitation of aqueous metal salt solutions (e.g., nitrates) with sodium carbonate solution. Precipitation may occur in one or several stages. The quality of the subsequent catalyst is determined by the optimum composition of the metal components, the precipitation temperature, the pH used for precipitation, the sequence of metal salt additions, and the duration of precipitation. The stirring rate, stirring energy, and shape of stirrer also affect catalyst quality.

The precipitated catalyst precursors (largely metal hydroxycarbonates) are filtered off from the mother liquor, washed free of interfering ions (e.g., sodium), and dried at ca. 120 °C. Examples of such hydroxycarbonates are malachite rosasite $(Cu,Zn)_5(CO_3)(OH)_2$, hydrozincite $(Cu,Zn)_5(OH)_6(CO_3)_2$, and aurichalcite $(Cu_{0.3}Zn_{0.7})_5(OH)_6(CO_3)_2$ [40], [47], [82]. Aurichalcite derivatives with the composition $Cu_{2.2}Zn_{2.8}(OH)_6(CO_3)_2$, containing small amounts of alumina for stabilization, are obtained by coprecipitation of metal nitrates [87], [88]. The catalyst precursor is converted to finely divided metal oxide by subsequent calcination at ca. 300 – 500 °C [80]. The calcined product is then pelleted to commercial catalyst forms. Cylindrical tablets 4 – 6 mm in diameter and height are common [46], [47], [82], [89].

The catalysts still have a total BET surface area of 60 – 100 m^2/g and have to be activated [47]. They are activated by controlled reduction with 0.5 – 2 % hydrogen in nitrogen at 150 –230 °C. Particular care must be taken to avoid hot spots, which lead to premature catalyst aging. In their reduced (i.e., active) form, the synthesis-active copper surfaces of commercial catalysts have a surface area of 20 – 30 m^2/g [81].

Catalysts for the low-pressure synthesis of methanol can also be produced by other methods, e.g., impregnating a carrier with active components, kneading metal compounds together, and leaching Raney alloys [17], [82].

Catalysts must be devoid of interfering impurities. Alkali compounds reduce the useful life and adversely affect the selectivity of catalysts. Even iron or nickel impurities in the parts-per-million range promote the formation of hydrocarbons and waxes. Acidic compounds such as silicon dioxide increase the proportion of dimethyl ether in crude methanol [90].

4.2.4. Catalyst Deactivation

As mentioned in Section 4.1, efficient catalysts for low-pressure synthesis of methanol should have a highly disperse distribution of active centers stabilized by structural promoters. The longer a catalyst can retain these properties under industrial conditions, the more valuable it is for industrial operation: downtimes for catalyst replacement are reduced. Catalysts normally have useful lives of 2 – 5 years. Many factors can drastically reduce catalyst activity and, thus, useful life. Detailed review articles on catalyst deactivation and poisoning can be found in [40], [47], [90].

Even during catalyst production, manufacturing faults can seriously affect the complex structure of the active centers (see Section 4.2.3). Catalyst damage and, consequently, premature deactivation may also occur during reduction. The temperature conditions, hydrogen concentration of the reducing gas, and gas load must be strictly controlled. Deviations from specified reduction procedures may lead to hot spots in the pellets, resulting in sintering of the copper constituents; copper becomes mobile at 190 °C and can agglomerate from its finely divided form into fairly

Table 4. Summary of typical copper-containing catalysts for low-pressure methanol synthesis

Manufacturer	Component	Content, atom%	Reference
IFP	Cu	25 – 80	[83]
	Zn	10 – 50	
	Al	4 – 25	
Süd Chemie	Cu	65 – 75	[84]

Haldor Topsoe	Cu	37	[88]
	Zn	15	
	Cr	48	

large crystallites. Reduction must be complete to obtain the entire active mass from the precursor compounds (see Section 4.2.3). Deviations from the specified reduction conditions may permanently decrease the active BET surface area and thus irrevocably damage the catalyst.

Another important point regarding the deactivation of copper catalysts is their high sensitivity to impurities in synthesis gas. Chlorine- and sulfur-containing contaminants long prevented the use of copper-containing catalyst systems in industrial methanol plants. These catalyst poisons must be removed from the feed gas prior to methanol synthesis. A certain degree of protection against deactivation by sulfur is afforded by catalysts containing zinc oxide because the sulfur is bound as zinc sulfide. After deactivation, the catalyst is still able to absorb large quantities of sulfur to protect subsequent catalyst layers against poisoning. Other synthesis gas impurities (e.g., silicon compounds, nickel carbonyls, or iron carbonyls) also cause catalyst damage [90].

The catalyst can also be deactivated by overheating during operation. Thermal damage to the catalyst can occur after use of nonoptimum recycled gas compositions, incorrect temperature control, or overloaded catalyst in the startup phase. The active surface area of the catalyst is decreased and phase transformations occur. The formation of copper spinels as well as malachite rosasite is observed. In effect, this removes active centers for methanol synthesis from the catalyst [40], [45], [91].

4.2.5. Other Catalyst Systems

A number of modified copper – zinc oxide – alumina catalysts have been prepared by doping with boron, manganese, cerium, chromium, vanadium, magnesium, or other elements [92–100]. Other basic types of catalyst systems have also been investigated: Raney copper catalysts, copper alloys with thorium or rare-earth oxides, and supported precious-metal catalysts [101–106]. Only copper alloy catalysts are reported to have a higher activity than conventional copper – zinc oxide – alumina catalysts [107]. Until now, however, exclusively copper-containing zinc oxide – alumina catalysts have been used in industrial methanol plants. These catalysts have high activity, very good selectivity, long-term stability, and favorable production

costs. They are still the most cost effective catalysts.

5. Process Technology

The oldest process for the industrial production of methanol is the dry distillation of wood, but this no longer has practical importance (→ Biomass Chemicals, Chap. 4.9.). Other processes, such as the oxidation of hydrocarbons and production as a byproduct of the Fischer – Tropsch synthesis according to the Synthol process, have no importance today.

Methanol is currently produced on an industrial scale exclusively by catalytic conversion of synthesis gas. Processes are classified according to the pressure used:

1) High-pressure process 25 – 30 MPa
2) Medium-pressure process 10 – 25 MPa
3) Low-pressure process 5 – 10 MPa

The main advantages of the low-pressure process are lower investment and production costs, improved operational reliability, and greater flexibility in the choice of plant size.

Industrial methanol production can be subdivided into three main steps:

1) Production of synthesis gas
2) Synthesis of methanol
3) Processing of crude methanol

5.1. Production of Synthesis Gas

All carbonaceous materials such as coal, coke, natural gas, petroleum, and fractions obtained from petroleum (asphalt, gasoline, gaseous compounds) can be used as starting materials for synthesis gas production. Economy is of primary importance with regard to choice of raw materials. Long-term availability, energy consumption, and environmental aspects must also be considered.

Natural gas is generally used in the large-scale production of synthesis gas for methanol synthesis. In a few processes (e.g., acetylene production), residual gases are formed which have roughly the composition of the synthesis gas required for methanol synthesis.

Synthesis gases are characterized by the stoichiometry number S:

$$S = \frac{[H_2] - [CO_2]}{[CO] + [CO_2]}$$

where the concentrations of relevant components are expressed in volume percent. The stoichiometry number should be at least 2.0 for the synthesis gas mixture. Values above 2.0 indicate an excess of hydrogen, whereas values below 2.0 mean a hydrogen deficiency relative to the stoichiometry of the methanol formation reaction.

Natural Gas. Most methanol produced worldwide is derived from natural gas. Natural gas can be cracked by steam reforming and by partial oxidation (Fig. 2, see also → Ammonia).

In *steam reforming* the feedstock is catalytically cracked in the absence of oxygen with the addition of water and possibly carbon dioxide (→ Gas Production, Chap. 2.→ Gas Production, Chap. 7.1.). The reaction heat required is supplied externally. In *partial oxidation,* cracking takes place without a catalyst (→ Gas Production, Chap. 3.2.). Reaction heat is generated by direct oxidation of part of the feedstock with oxygen. In a combination of the two processes, only part of the natural gas stream is subjected to steam reforming [108]. The remainder passes with the reformed gas to an autothermal reformer where the natural gas is partially oxidized by oxygen.

Only the production of synthesis gas by steam reforming is discussed here in some detail.

The catalysts used in steam reforming are extremely sulfur sensitive; sulfur concentrations < 0.5 ppm quickly poison the catalyst. A gas purification stage therefore precedes the reformer stage. If sulfur occurs primarily in the form of higher boiling compounds (e.g., mercaptans), batchwise adsorption on a regenerable activated charcoal bed is recommended. In the case of hydrogen sulfide, zinc oxide is used as adsorbent to remove sulfur as zinc sulfide at 340 – 370 °C. Hydrogenating desulfurization becomes necessary if organic sulfur compounds (e.g., COS) are present that cannot be removed with charcoal. Hydrogen (e.g., in the form of purge gas from methanol synthesis) is mixed with the gas stream to be desulfurized and passed over a cobalt or nickel – molybdenum catalyst at 290 – 370 °C.

Figure 2. Processes for producing synthesis gases

The sulfur compounds are converted into hydrogen sulfide, which can be removed in a subsequent zinc oxide column.

In the reformer, natural gas is catalytically cracked in the presence of steam:

$$CH_4 + H_2O \rightleftharpoons CO + 3\,H_2 \quad \Delta H_{300\,K} = 206.3\,\text{kJ/mol}$$

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad \Delta H_{300\,K} = -41.2\,\text{kJ/mol}$$

The first of these reactions is endothermic and leads to an increase in volume, whereas the second is exothermic and proceeds without change in volume. The degree of conversion of methane increases with increasing temperature, increasing partial pressure of steam, and decreasing absolute pressure.

The interfering Boudouard equilibrium

$$2\,CO \rightleftharpoons CO_2 + C \quad \Delta H_{300\,K} = -172.6\,\text{kJ/mol}$$

which would lead to carbon deposits on the catalyst or on the walls of reformer tubes, can largely be prevented by using excess steam and avoiding long residence times in the critical temperature range above 700 °C.

To reach the stoichiometry necessary for methanol synthesis, carbon dioxide, if available, is mixed with exit gas from the steam reformer. If carbon dioxide is not available, the conversion must be performed with an excess of hydrogen. Hydrogen accumulates in the synthesis recycle gas and must be removed.

Other Raw Materials. Natural gas is not the only raw material for synthesis gas used in methanol production plants. Higher hydrocarbons (e.g., liquefied petroleum gas, refinery off-gases, and particularly naphtha) are also used (→ Gas Production, Chap. 2.1.); they are processed mainly by steam reforming. Crude oil, heavy oil, tar, and asphalt products (→ Gas Production, Chap. 3.1.) can also be converted into synthesis gas, but this is more difficult than with natural gas. Their sulfur content is considerably higher (0.7 – 1.5 % H_2S and COS) and must be removed. Synthesis gas also contains excess carbon monoxide and must, therefore, be subjected to shift conversion.

Coal can be converted into synthesis gas with steam and oxygen by a variety of processes at different pressures (0.5 – 8 MPa) and temperature (400 – 1500 °C); see also → Coal, Chap. 9.4.; → Gas Production, Chap. 4. Synthesis gas must be desulfurized and subjected to shift conversion to obtain the required stoichiometry for methanol synthesis.

5.2. Synthesis

Important reactions (Eqs. 1 – 3) for the formation of methanol from synthesis gas are discussed in Section 4.1. In one pass only about 50 % of the synthesis gas is converted because thermodynamic equilibrium is reached; therefore, after methanol and water are condensed out

and removed, the remaining synthesis gas must be recycled to the reactor. A simplified flow diagram for methanol synthesis is shown in Figure 3. The make-up synthesis gas is brought to the desired pressure (5 – 10 MPa) in a multistage compressor (f). The unreacted recycle is added before the recycle stage. A heat exchanger (b) transfers energy from the hot gas leaving the reactor to the gas entering the reactor. The exothermic formation of methanol takes place in the reactor (a) at 200 – 300 °C. The heat of reaction can be dissipated in one or more stages. The mixture is cooled further (c) after passing through the heat exchanger (b); the heat of condensation of methanol and water can be utilized at another point in the process.

Figure 3. Methanol synthesis
a) Reactor; b) Heat exchanger; c) Cooler; d) Separator; e) Recycle compressor; f) Fresh gas compressor

Crude methanol is separated from the gas phase in a separator (d) and flashed before being distilled. Gas from the separator is recycled to the suction side of the recycle compressor (e). The quantity of purge gas from the loop is governed by the concentration and absolute amount of inert substances and the stoichiometry number. If hydrogen is used to adjust the composition of the fresh gas to give the required stoichiometry number it can be recovered from the purge gas by various methods (e.g., pressure swing absorption). The purge gas is normally used for reformer heating.

5.3. Reactor Design

Current industrial processes for producing methanol differ primarily in reactor design. Many different reactors are available [109]; they may be either adiabatic (e.g., ICI) or quasi-isothermal (e.g., Lurgi). The ICI process (Fig. 4) accounts for 60 %, and the Lurgi process (Fig. 5) for 30 % of worldwide methanol production.

Adiabatic Reactors. The ICI process (Fig. 4) uses an adiabatic reactor with a single catalyst bed [110]. The reaction is quenched by adding cold gas at several points. Thus, the temperature profile along the axis of the reactor has a sawtooth shape.

In the Kellogg process, synthesis gas flows through several reactor beds that are arranged axially in series [111]. In contrast to the ICI quench reactor, the heat of reaction is removed by intermediate coolers. The Haldor Topsoe reactor operates on a similar principle, but synthesis gas flows radially through the catalyst beds [112].

Ammonia – Casale S. A. has developed a reactor that employs a combination of axial and radial flow (mixed flow). This type of reactor initially developed for ammonia plants is offered by Davy McKee in ICI license [113].

Quasi-Isothermal Reactors. The Lurgi process (Fig. 5) employs a tubular reactor (f) with cooling by boiling water [114]. The catalyst is located in tubes over which water flows. The temperature of the cooling medium is adjusted by a preset pressure.

The Variobar reactor developed by Linde [115] consists of a shell-and-tube reactor coiled in several tiers, whose cooling tubes are embedded in the catalyst packing. The reactor temperature is adjusted by water cooling. As in other processes, the heat of reaction is utilized to produce steam, which can be used, for example, to drive a turbine for the compressor or as an energy source for subsequent methanol distillation.

Whereas synthesis gas flows axially through the two above-mentioned reactors, Toyo offers a reactor through which it flows radially [116]. The advantages, as in the Variobar reactor, lie in a high heat transfer rate with only slight pressure loss.

The Mitsubishi Gas Chemical (MGC) process uses a reactor with double-walled tubes that are filled in the annular space with catalyst [117]. The synthesis gas first flows through the inner tube to heat it up and then, in countercurrent, through the catalyst between the two tubes. The

Figure 4. The ICI low-pressure methanol process

outer tubes are cooled by water, Mitsubishi considers the main advantage of this process to be the high conversion rate (ca. 14 % methanol in the reactor outlet).

5.4. Distillation of Crude Methanol

Crude methanol leaving the reactor contains water and other impurities (see Section 4.1). The amount and composition of these impurities depend on reaction conditions, feed gas, and type and lifetime of the catalyst. Crude methanol is made slightly alkaline by the addition of small amounts of aqueous caustic soda to neutralize lower carboxylic acids and partially hydrolyze esters.

The methanol contains low-boiling and high-boiling components (light and heavy ends). The light ends include dissolved gases, dimethyl ether, methyl formate, and acetone. The heavy ends include higher alcohols, long-chain hydrocarbons, higher ketones, and esters of lower alcohols with formic, acetic, and propionic acids. Higher waxy hydrocarbons consisting of a mixture of mostly straight-chain $> C_8 - C_{40}$ compounds are also formed in small amounts. They have low volatility and thus remain in the distillation bottoms, from which they can easily be removed because of their low solubility in water and low density.

The impurities in crude methanol are generally separated in two stages. First, all components boiling at a lower temperature than methanol are removed in a light ends column (Fig. 4 b, Fig. 5 b). Pure methanol is then distilled overhead in one or more distillation columns (Fig. 4 a, Fig. 5 a). If the columns operate at different pressures, the heat of condensation of the vapors of the column operating at higher pressure can be used to heat the column at lower pressure.

5.5. Construction Materials

Low-molybdenum steels are normally used as construction materials in methanol synthesis. Because organic acids are especially likely to be encountered in the methanol condensation stage, stainless steels are generally used then. Damage due to acids can also be prevented by the addition of small amounts of dilute caustic soda.

Stainless steels are normally employed in equipment operating at temperatures in which the formation of iron pentacarbonyl is likely (i.e., 100 – 150 °C). This applies, for example, to heat exchangers and compressors. Contamination with iron pentacarbonyl should be avoided because it decomposes at the temperatures used for methanol synthesis. Iron deposited on the catalyst poisons it and promotes the formation of higher hydrocarbons (waxy products).

6. Handling, Storage, and Transportation

6.1. Explosion and Fire Control

The flammability of methanol and its vapors represents a potential safety problem. The flash point is 12.2 °C (closed cup) and the ignition temperature 470 °C; in the Federal Republic of Germany methanol is thus included in ignition group B of the VbF [119].

Methanol vapor is flammable at concentrations of 5.5 – 44 vol %. The saturated vapor pressure at 20 °C is 128 kPa; a saturated methanol – air mixture is thus flammable over a wide temperature range. Methanol is included in ignition group G1, explosion class 1 (ExRL).

In premises and workshops in which the presence of methanol vapor is likely, electrical equipment must be designed in accordance with the relevant regulations:

Guidelines for explosion protection (ExRL)
Regulations governing electrical equipment in explosionhazard areas (ElE × V)
DIN VDE 0165
DIN EN 50 014 – 50 020

For international guidelines on the handling of methanol publications of the Manufacturing Chemists' Association should be consulted [118].

Pure, anhydrous methanol has a very low electrical conductivity. Measures to prevent electrostatic charging must therefore be adopted when transferring and handling methanol.

Fire Prevention. The VbF restrictions on the amount of methanol that can be stored in laboratory premises should be observed. When large amounts of methanol are stored in enclosed

spaces, monitoring by means of lower explosion limit monitors is desirable.

Permanently installed fire-extinguishing equipment should be provided in large storage facilities. Water cannons are generally installed in storage tank farms to cool steel constructions and neighboring tanks in the event of fire. Large tanks should have permanently installed piping systems for alcohol-resistant fire-extinguishing foams.

Fire Fighting. Conventional fire-extinguishing agents such as powder, carbon dioxide, or Halon can be used for small fires. Water is unsuitable as an extinguishing agent for fires involving large amounts of methanol because it is miscible with the compound; mixtures containing small amounts of methanol may also burn. Protein-based alcohol-resistant foams are suitable.

A methanol flame is practically invisible in daylight, which complicates fire fighting. The methanol flame does not produce soot, although formaldehyde and carbon monoxide form during combustion when oxygen is lacking. Respirators must therefore be worn when fighting fires in enclosed areas.

6.2. Storage and Transportation

Small-Scale Storage. Fairly small amounts (≤ 10 L) of methanol for laboratory and industrial use are stored in glass bottles or sheet-metal cans; amounts up to 200 L are stored and transported in steel drums. Some plastic bottles and containers cannot be used because of their permeability and the danger of dissolution of plasticizers. High-density polyethylene and polypropylene are suitable, whereas poly(vinyl chloride) and polyamides are unsuitable.

Large-Scale Storage. Large amounts of methanol are stored in tanks that correspond in design and construction to those used for petroleum products; cylindrical tanks with capacities from a few hundred cubic meters to more than 100 000 m^3 are normally used. With fixed-roof tanks, special measures (e.g., nitrogen blanketing) should be adopted to prevent the formation of an ignitable atmosphere in the space above the liquid surface. Emission of methanol may occur if the level fluctuates. To avoid these problems, large tanks are often equipped with floating roofs; attention should therefore be paid to guard against entry of rainwater.

For anhydrous and carbon dioxide-free methanol tanks, pipelines and pumps can be constructed from normal-grade steel; seals can be made from mineral fiber, graphite, and metal. Styrene – butadiene rubber, chlorine – butadiene rubber, and butyl – chlorobutyl rubber can be used for shaft seals.

Table 5. Federal specifications for pure methanol in the United States

Property	Grade A	Grade AA
Ethanol content, mg/kg		< 10
Acetone content, mg/kg		< 20
Total acetone and aldehyde content, mg/kg	< 30	< 30
Acid content (as acetic acid), mg/kg	< 30	< 30
Color index (APHA)	< 5	< 5
Sulfuric acid test (APHA)	< 30	< 30
Boiling point range (101.3 kPa), must include 64.6 ± 0.1 °C	< 1	< 1
Dry residue, mg/L	< 10	< 10
Density (20 °C), g/cm^3	0.7928	0.7928
Permanganate number	> 30	> 30
Methanol content, wt %	> 99.85	> 99.85
Water content, wt %	< 0.15	< 0.10
Odor	typical, non-persistent	

Large-Scale Transportation. Methanol is traded worldwide. The recent trend toward relocating production to sites that are remote from industrial centers where inexpensive natural gas is available, has meant that ca. 30 % of methanol produced worldwide must be transported by sea to consumer countries (Japan, Europe, United States). Specially built tankers with capacities up to 40 000 t are available for this purpose; ships built to transport petroleum products are also used.

The most important European transshipment point for methanol is Rotterdam. Methanol is distributed to inland industrial regions mainly by inland waterways on vessels with capacities up to 3000 t. Boats specialized for methanol transport are the exception; impurities can therefore be introduced into the methanol due to frequent change of cargo. Analysis prior to delivery is generally essential.

Methanol is also transported by road and rail tank cars. Permanently coupled trains consisting

of several large tank cars with common filling, discharge, and ventilation lines are used to supply large customers.

Transportation via pipeline is only of importance for supplying individual users within enclosed, self-contained chemical complexes.

Safety Regulations Governing Transportation. The transportation of methanol as less-than-carload freight in appropriate vessels, containers, and bulk, is governed by specific regulations that differ from country to country. An effort is being made, and is already well advanced, to coordinate these regulations within the EC. Relevant legal regulations governing less-than-carload and bulk transportation by sea, on inland waterways, and by rail, road, and air are as follows [120]:

IMDG Code (D-GGVSee)	D 3328/E-F 3087, Class 3.2, UN No. 1230
RID (D-GGVE)	Class 3, Rn 301, Item 5
ADR (D-GGVS)	Class 3, Rn 2301, Item 5
ADNR	Class 3, Rn 6301, Item 5, Category Kx
European Yellow Book	No. 603-001-00-X
EC Guideline/D VgAst	No. 603-001-00-X
FRG (Land, VbF)	B
Great Britain	Blue Book: flammable liquid and IMDG Code E 3087
United States	CRF 49, Paragraph 172.1.1, flammable liquid
IATA	RAR, Art. No. 1121/43, flammable liquid

In addition to water, typical impurities include acetone (which is very difficult to separate by distillation) and ethanol. When methanol is delivered by ships or tankers used to transport other substances, contamination by the previous cargo must be expected.

Comparative ultraviolet spectroscopy has proved a convenient, quick test method for deciding whether a batch can be accepted and loaded. Traces of all chemicals derived from aromatic parent substances, as well as a large number of other compounds, can be detected.

Further tests for establishing the quality of methanol include measurements of boiling point range, density, permanganate number, turbidity, color index, and acid number. More comprehensive tests include water determination according to the Karl Fischer method and gas chromatographic determination of byproducts. However, the latter is relatively expensive and time consuming because several injections using different columns and detectors must be made due to the variety of byproducts present.

The most important standardized test methods for methanol are

DIN 51 757	density
ASTM D 941	density
ASTM D 1078	boiling range
ASTM D 1209	color index
ASTM D 1353	dry residue
ASTM D 1363	permanganate number
ASTM D 1364	water content
ASTM D 1612	acetone content
ASTM D 1613	acid content

7. Quality Specifications and Analysis

Methanol for Laboratory Use. Methanol is available commercially in various purity grades for fine chemicals:

1) "Synthesis" quality (corresponding to normal commercial methanol)
2) Certified analytical quality
3) Extremely pure qualities for semiconductor manufacture

Commercial Methanol. In addition to laboratory grades, commercial methanol is generally classified according to ASTM purity grades A and AA (Table 5). Methanol for chemical use normally corresponds to Grade AA.

Apart from pure methanol, methanol obtained directly from synthesis without any purification, or with only partial purification, is sometimes used. This crude methanol can be used for energy (fuel methanol), for the manufacture of synthetic fuels, and for specific chemical and technical purposes; it is not normally available commercially. Composition varies according to synthesis conditions; principal impurities include, 5 – 20 vol % water, higher alcohols, methyl formate, and higher esters. The presence of water and esters can cause corrosion during storage due to the formation of organic acids (see Section 6.2); remedies include alkaline adjustment with sodium hydroxide and, if necessary, the use of corrosion-resistant materials.

8. Environmental Protection

Methanol is readily biodegraded; most microorganisms possess the enzyme alcohol dehydrogenase, which is necessary for methanol oxidation. Therefore, no danger exists of accumulation in the atmosphere, water, or ground; the biological stages of sewage treatment plants break down methanol almost completely. In the Federal Republic of Germany methanol has been classified as a weakly hazardous compound in water hazard Class 1 (WGK I, § 19 Wasserhaushaltsgesetz). In accidents involving transport, large amounts of methanol must be prevented from penetrating into the groundwater or surface waters to avoid contaminating drinking water. Little is known about the behavior of methanol in the atmosphere. Emissions occurring during industrial use are so small that harmful influences can be ignored. That situation could alter, however, if methanol were used on a large scale as an alternative to petroleum-based fuels.

In methanol production, residues that present serious environmental problems are not generally formed. All byproducts are used when possible; for example, the condensate can be processed into boiler feedwater, and residual gases or low-boiling byproducts can be used for energy production. The only regularly occurring waste product that presents some difficulties is the bottoms residue obtained after distillation of pure methanol; it contains water, methanol, ethanol, higher alcohols, other oxygen-containing organic compounds, and variable amounts of paraffins. The water-soluble organic substances readily undergo biological degradation; the insoluble substances can be incinerated safely in a normal waste incineration unit. In some cases this residual water is also subjected to further distillative purification; the resultant mixture of alcohols, esters, ketones, and aliphatics can be added in small amounts to carburetor fuel.

The spent catalysts contain auxiliary agents and supports, as well as copper (synthesis), nickel (gas generation), and cobalt and molybdenum (desulfurization) as active components. These metals are generally recovered or otherwise utilized.

Modern steam reformers can be fired so that emission of nitrogen oxides (NO_x) in the flue gas is maintained below 200 mg/m^3 without having to use secondary measures.

9. Uses

9.1. Use as Feedstock for Chemical Syntheses

Approximately 70 % of the methanol produced worldwide is used in chemical syntheses: in order of importance formaldehyde, methyl *tert*-butyl ether (MTBE), acetic acid, methyl methacrylate, and dimethyl terephthalate. Only a small proportion is utilized for energy production, although this use has great potential.

Formaldehyde. Formaldehyde is the most important product synthesized from methanol (→ Formaldehyde, Chap. 4.); in 1988, 40 %; in 1996 35 %, of the methanol produced worldwide was used to synthesize this product. The annual estimated increase in formaldehyde production from methanol is ca. 3 %, but because other bulk products have higher growth rates its share as a proportion of methanol use will decrease.

The processes employed are all based on the oxidation of methanol with atmospheric oxygen. They differ mainly with regard to temperature and nature of the catalyst used.

Methyl *tert*-butyl ether is produced by reacting methanol with isobutene on acid ion exchangers (→ Methyl tert-Butyl Ether). Increasing amounts of methanol are used in this form in the fuel sector. The ether is an ideal octane booster and has become extremely important due to the introduction of unleaded grades of gasoline and awareness of the possible harmfulness of aromatic high-octane components. In 1988, 20 %; in 1996 27 %, of worldwide methanol production was used for MTBE synthesis; annual increase rates of up to 12 % are expected. The availability of isobutene is becoming an increasing problem in MTBE synthesis, although the situation has recently been improved by the construction of plants for the isomerization of butane and subsequent dehydrogenation of isobutane.

Acetic Acid. Another 9 % of the methanol produced is used to synthesize acetic acid, and annual growth rates of 6 % are estimated. Acetic acid is produced by carbonylation of methanol with carbon monoxide in the liquid phase with cobalt – iodine, rhodium – iodine, or nickel – iodine homogeneous catalysts (→ Acetic Acid, Chap. 4.1.). The older BASF process operates at 65 MPa, whereas more modern processes (e.g., the Monsanto process) operate at 5 MPa. By varying operating conditions the synthesis can also be modified to produce acetic anhydride or methyl acetate.

Other Synthesis Products. In the intensive search after the oil crisis for routes to alternative fuels, processes were developed that allowed fuels to be produced from synthesis gas with methanol as an intermediate. Mobil in the United States has contributed decisively to the development of such processes, which involve mainly the reaction of methanol on zeolite catalysts. The most important and, up to now, the only industrially implemented process is methanol to gasoline (MTG) synthesis. A plant for producing and converting 4500 t/d of methanol from natural gas into 1700 t/d of gasoline has been built and operated as a joint venture between the New Zealand government and Mobil. Since the prices of petroleum products have not risen as expected, ways are now being sought to process the methanol from this plant into pure methanol and to market it as such.

Further synthesis routes that could become important in the event of a scarcity of petroleum products are the methanol to olefins (MTO) and methanol to aromatic compounds (MTA) processes [121].

A product that received great attention as a result of the discussion of environmental damage caused by chlorofluorocarbons is dimethyl ether (→ Dimethyl Ether). It can be used as an alternative propellant for sprays. Compared to propane – butane mixtures also used as propellants, its most important feature is its higher polarity and, thus, its better solubilizing power for the products used in sprays. Dimethyl ether is also used as a solvent, organic intermediate, and in adhesives.

Methanol is used to synthesize a large number of other organic compounds:

Formic acid	preservatives, pickling agents
Methyl esters of organic acids	solvents, monomers
Methyl esters of inorganic acids	methylation reagents, explosives, insecticides
Methylamines	pharmaceutical precursors, auxiliaries, absorption liquids for gas washing and scrubbing
Trimethylphosphine	pharmaceuticals, vitamins, fragrances, fine chemicals
Sodium methoxide	organic intermediates, catalyst
Methyl halides	organic intermediates, solvents, propellants
Ethylene	organic intermediates, polymers, auxiliaries (→ Ethylene)

9.2. Use as Energy Source

Methanol is a promising substitute for petroleum products if they become too expensive for use as fuels. As a result of the oil crisis in the early 1970s, a number of projects were started based on the assumption that the use of methanol produced from coal would be more economical in the medium term than the use of petroleum products. The estimates made at the beginning of the 1980s proved to be too optimistic, however, with regard to costs and to overcoming technical or environmental problems involved in producing synthesis gas from coal, and too pessimistic with regard to the price and availability of crude oil (Table 6). Nearly all the large-scale projects for coal utilization have been discontinued. Large-scale operational plants (e.g., Cool Water, United States and Rheinbraun, Wesseling, FRG) are being shut down or modified for use with other feedstocks [122].

Methanol as a Fuel for Otto Engines. The use of methanol as a motor fuel has been discussed repeatedly since the 1920s. Use has so far been restricted to high-performance engines for racing cars and aeroplanes. The combustion of methanol in four-stroke engines has been investigated for a long time. Methanol has been found to be an ideal fuel in many respects. Because of its high heat of vaporization and relatively low calorific value, a substantially lower combustion chamber temperature is achieved than with conventional motor fuels. Emissions of nitrogen oxides, hydrocarbons, and carbon monoxide are lower. This is offset, however, by increased emission of formaldehyde.

Table 6. Comparison of the efficiencies of natural gas conversion in liquid fuels

Energy carrier	Higher heating value, Gcal/t	Yield, t/t CH_4	Higher heating value, Gcal/t CH_4	Theoretical efficiency	Stoichiometric factor, [H] – [20]/[C]	Technical efficiency ∗ ∗
Methane	13.2	1	13.28	100	4	
Synthesis gas, partial oxidation	6.36	2	12.70	95.7	2	85 – 90
Synthesis gas, steam reforming	7.96	2.12 ∗	16.91 ∗		6	
Methanol	5.36	2	10.72	80.7	2	68 – 72
Ethanol	7.14	1.43	10.25	77.2	2	
Kerosene	11.00	0.87	9.57	72.1	ca. 2.05	
Diesel fuel	10.70	0.87	9.34	70.4	ca. 2	55 – 60 FT
Gasoline (average)	10.50	0.86	9.06	68.2	ca. 1.8	58 – 63 MTG 55 – 60 FT
Benzene	10.02	0.81	8.13	61.2	1	

∗ With extra heat energy for reformer.
∗ ∗ FT = Fischer – Tropsch; MTG = methanol to gasoline.

Table 7. Comparison of methanol and a typical fuel (gasoline) for use in Otto engines

Property	Gasoline	Methanol
Density, kg/L	0.739	0.793
Calorific value, kJ/kg	44 300	21 528
Air consumption, kg/kg	14.55	6.5
Research octane number	97.7	108.7
Motor octane number	89	88.6
Mixed research octane number		120 – 130
Mixed motor octane number		91 – 94
Reid vapor pressure, kPa	64	32
Boiling point range, °C	30 – 190	65
Heat of vaporization, kJ/kg	335	1174
Cooling under vaporization with stoichiometric amount of air, °C	20	122

The important properties of methanol for use as a fuel are compared with those of a conventional fuel (gasoline) in Table 7. Consumption is higher because of the lower calorific values.

Methanol can be used in various mixing ratios with conventional petroleum products:

M 3 Mixture of 3 % methanol with 2 – 3 % solubilizers (e.g., isopropyl alcohol) in commercially available motor fuel. This system is already widely used because modification of motor vehicles and fuel distribution systems is not required.

M 15 Mixture of 15 % methanol and a solubilizer with motor fuel; alterations to the motor vehicles are necessary in this case. The proposed use of M 15 to increase the octane number in unleaded gasoline has been supplanted by the large increase in the use of MTBE.

M 85 Methanol containing 15 % C_4–C_5 hydrocarbons to improve cold-start properties. Modified vehicles and fuel distribution systems are necessary.

M 100 Pure methanol–vehicles must be substantially modified and fully adapted to methanol operation.

The necessary modifications for methanol operation involve the replacement of plastics used in the fuel system (see Section 6.2). The ignition system and carburetor or fuel injection unit also have to be adapted. With M 85 and M 100 the fuel mixture must be preheated because vaporization of the stoichiometric amount of methanol in the carburetor results in a cooling of 120 K.

In mixtures with a low methanol content (M 3, M 15) phase separation in the presence of traces of water must be avoided. Absolutely dry storage, transportation, and distribution systems must be available for mixed fuels to prevent separation of water – methanol and hydrocarbon phases.

A further restriction on the use of methanol in gasoline is imposed by the increase in gasoline vapor pressure (Reid vapor pressure, RVP). In some warm regions of the United States, legal restrictions on the RVP have already been introduced to reduce hydrocarbon emissions, which are an important factor in the formation of photochemical smog and increased ozone concentration in the lower atmosphere. As a result, methanol can not longer be added to motor fuel because it increases the vapor pressure of the butane used as a cheap octane booster.

Widespread use of methanol as an exclusive fuel for cars is inhibited by its high cost and the lack of a suitable distribution system. Possible solutions to the latter problem include the construction of dual-purpose vehicles (flexible fuel vehicles), which can use either methanol or nor-

mal fuel. Another solution is to use methanol for company or government car fleets, which refill their tanks at a few specific filling stations. Trials based on this concept are underway in several countries; the largest is taking place in California [123].

Methanol as Diesel Fuel. Exclusive operation with methanol is not possible in diesel engines because methanol has a cetane number of 3 and will therefore not ignite reliably. To ensure ignition the engine must have an additional injector for normal diesel fuel; methanol is injected into the cylinder after ignition of the diesel fuel [124]. Additives are being developed to improve ignition performance.

Other Uses of Methanol in the Fuel Sector. In contrast to pure methanol, the use of MTBE in Otto engine fuels is not limited by considerations of miscibility or vapor pressure. The use of methanol for MTBE synthesis could soon quantitatively overtake its conventional uses. Arco, the world's largest producer of MTBE, is also promoting the use of oxinol, a mixture of methanol and *tert*-butanol.

An additional development in the use of methanol is the Lurgi Octamix process. Use of an alkali-doped catalyst and modified conditions (higher temperature, lower CO_2 concentration, higher CO concentration) in methanol synthesis yields a mixture of methanol, ethanol, and higher alcohols [125]. This mixture can be used directly in the engine fuel. The presence of higher alcohols is desirable not only because of the increase in octane number, but also because they act as solubilizers for methanol. However, this process is not yet used on an industrial scale.

Other Energy Uses of Methanol. A use that has been discussed particularly in the United States and implemented in pilot projects is the firing of peak-load gas turbines in power stations (peak shaving). Benefits include simple storage and environmentally friendly combustion in the gas turbine. The use of methanol as a fuel in conventionally fired boilers obviates the need for costly flue gas treatment plants but is not yet economically viable.

The gasification of methanol to obtain synthesis gas or fuel gas has often been proposed. Apart from exceptions such as the production of town gas in Berlin, here too, economic problems have prevented technical implementation.

9.3. Other Uses

Methanol's low freezing point and its miscibility with water allow it to be used in *refrigeration systems,* either in pure form (e.g., in ethylene plants) or mixed with water and glycols. It is also used as an *antifreeze* in heating and cooling circuits; compared to other commonly used antifreezes (ethylene glycol, propylene glycol, and glycerol), it has the advantage of lower viscosity at low temperature. It is, however, no longer used as an engine antifreeze; glycol-based products are employed instead.

Large amounts of methanol are used *to protect natural gas pipelines* against the formation of gas hydrates at low temperature. Methanol is added to natural gas at the pumping station, conveyed in liquid form in the pipeline, and recovered at the end of the pipeline. Methanol can be recycled after removal of water taken up from natural gas by distillation.

Methanol is also used as an *absorption agent* in gas scrubbers. The removal of carbon dioxide and hydrogen sulfide with methanol at low temperature (Rectisol process, Linde and Lurgi) has the advantage that traces of methanol in the purified gas do not generally interfere with further processing [126].

The use of pure methanol as a *solvent* is limited, although it is often included in solvent mixtures.

Figure 6. Worldwide methanol production
The estimate for 1989 – 1992 is based on a utilization of 80 % capacity [126], [127].

10. Economic Aspects

Economics of Methanol Production. The costs of methanol production depend on many factors, the most important being direct feedstock costs, investment costs, and costs involved in logistics and infrastructure.

Natural gas, naphtha, heavy heating oil, coal, and lignite are all used as feedstocks in methanol plants. In heavy oil-based plants and to an increasing extent in coal-based plants the principal cost burden is accounted for by capital costs. This means that, given the currently prevailing low energy prices, such plants have high fixed costs and are, therefore, uneconomical or economical only under special conditions. Under present conditions the balance between investment and operating costs clearly favors natural gas-based plants. All large plants currently being planned are designed for use with natural gas and some plants built for operation with naphtha have been converted. Less than 2×10^6 t of the currently installed worldwide capacity of ca. 21×10^6 t is based on raw materials other than natural gas.

Methanol on the World Market. After ammonia, methanol is quantitatively the largest product from synthesis gas. Worldwide capacity at the beginning of 1989 was 21×10^6 t. In 1988, 19×10^6 t of methanol was produced worldwide. The mean annual production growth rate is ca. 10 %. The production curve for methanol since 1965 is illustrated in Figure 6. Worldwide capacity in 1996 was 29.1×10^6 t/a, 24.3×10^6 t/a of methanol was produced.

The methanol industry underwent radical structural changes during the 1980s. Previously, companies that consumed large quantities of methanol produced the compound themselves from the most readily accessible raw materials at the site of use (i.e., highly industrialized countries with expensive energy sources). Since then the number of plants that produce methanol at remote sites exclusively for sale to processors has risen dramatically.

After the energy crisis of the 1970s, intensive oil prospecting led to the discovery of large natural gas fields in many remote regions. Because little demand for natural gas existed in these regions, the relevant countries in South America, Asia, and the Caribbean were interested in selling natural gas as such or in another form to industrialized countries.

Another, hitherto little-used energy source is the associated gas, which is often flared off. In addition to the transportation of liquefied methane and its use as a starting material for ammonia production, methanol production is often the most suitable alternative for marketing such gases. The technology of methanol production is relatively simple, and transport and storage involve inexpensive technology. On the basis of these considerations, 14 new natural gas-based plants producing methanol for export were built from 1974 to 1985 [128]. The largest single train plant based on this concept is located at Punta Arenas in southern Chile; it came on stream in 1988 and has an output of 750 000 t/a. As a consequence of this development, older methanol plants in industrialized countries such as the United States, Japan, and the Federal Republic of Germany have been shut down. The shift in capacities is illustrated in Figure 7.

Since a close relationship between supply and demand no longer exists, large price fluctuations occur, which are hardly justified by actual market conditions. This makes long-term price forecasts impossible and increases economic risks for new projects.

Figure 7. Distribution of existing and planned production capacity for methanol according to region [127]

11. Toxicology and Occupational Health

11.1. Toxicology

Human Toxicology. The first accounts of the poisonous action of "methylated spirits" were

published in 1855 [129]. However, the number of cases of poisoning increased only after the production of a low-odor methanol. In 1901, De Schweinitz reported the first cases of industrial poisoning [130].

Liquid methanol is fully absorbed via the gastrointestinal tract [131] and the skin [132] (absorption rate, 0.19 mg cm^{-2} min^{-1}). Methanol vapor is taken up in an amount of 70 – 80 % by the lungs [133]. The compound is distributed throughout body fluids and is largely oxidized to formaldehyde and then to formic acid [134]. It is eliminated unchanged through the lungs [132] and in the urine. Elimination half-life is ca. 2 – 3 h.

The metabolism of methanol to formic acid in humans and primates is catalyzed by the enzyme alcohol dehydrogenase in the liver. This enzyme can be inhibited competitively by ethanol. Formic acid is oxidized to carbon dioxide and water in the presence of folic acid. Because folic acid is not available in sufficient amount in primates, formic acid may accumulate in the body. This leads to hyperacidity of the blood (acidosis), which is ultimately responsible for methanol poisoning [134].

The symptoms of methanol poisoning do not depend on the uptake route (percutaneous, inhalational, oral) and develop in three stages. An initial narcotic effect is followed by a symptom-free interval lasting 10 – 48 h. The third stage begins with nonspecific symptoms such as abdominal pain, nausea, headache, vomiting, and lassitude, followed by characteristic symptoms such as blurred vision, ophthalmalgia, photophobia, and possibly xanthopsia. Depending on the amount of methanol, individual sensitivity, and the time when treatment is initiated, visual disturbances can either improve or progress within a few days to severe, often irreversible impairment of sight or even to blindness [136–139]. The symptoms are accompanied by increasing hyperacidity of the blood due to the accumulation of formic acid, with disturbances in consciousness, possibly deep coma, and in severe cases, death within a few days. The lethal dosage is between 30 and 100 mL per kilogram of body weight. Sensitivity to methanol varies widely, however. Cases have been reported in which no permanent damage occurred after drinking relatively large amounts of methanol (200 or 500 mL) [135], [140]; in another case, however, irreversible blindness resulted after consumption of 4 mL [141].

The treatment of acute oral methanol poisoning [137] should be initiated as quickly as possible with the following measures:

1) Administration of ethanol: In suspected cases of methanol poisoning, 30 – 40 mL of ethanol (e.g., 90 – 120 mL of whiskey) is administered immediately as a prophylactic before the patient is referred to a hospital. Because ethanol has a greater affinity for alcohol dehydrogenase than methanol, oxidation of methanol is inhibited; the production of formaldehyde and formic acid from methanol is thus suppressed.
2) Gastric lavage
3) Hemodialysis
4) Treatment with alkali: sodium bicarbonate is infused to control blood hyperacidity.
5) Administration of CNS stimulants (analeptics)
6) Drinking larger volumes of fluid
7) Eye bandage: the eyes should be protected against light
8) The patient should be kept warm

Methanol has a slight irritant action on the eyes, skin, and mucous membranes in humans. Concentrations between 1500 and 5900 ppm are regarded as the threshold value of detectable odor.

Chronic methanol poisoning is characterized by damage to the visual and central nervous systems. Case histories [142], [143] have not been sufficiently documented; whether poisoning is caused by chronic ingestion of low doses or ingestion of intermittently high (subtoxic) amounts is uncertain.

Animal Toxicology. Experiments on animals have shown that methanol does not cause acidosis or eye damage in nonprimates (e.g., rats, mice); it generally has a narcotic, possibly lethal, effect. Investigations on laboratory animals cannot, therefore, be extrapolated to humans, at least in the higher dosage range.

In a study on reproductive toxicology, methanol was administered to rats by inhalation during pregnancy. No embryotoxic effects were found after exposure to 5000 ppm [144]. The authors conclude that observance of the recommended

concentrations (MAK or TLV values) offers sufficient protection against fetal abnormalities in humans.

In the Ames test, the sex-linked lethal test on *Drosophila melanogaster* and the micronucleus test in mice, methanol was not mutagenic [145], [146].

11.2. Occupational Health

No special precautions need be taken when handling methanol because it is not caustic, corrosive, or particularly harmful environmentally. If methanol is released under normal conditions, no danger exists of buildup of acutely toxic concentrations in the atmosphere. (Chronic poisoning via the respiratory tract or oral ingestion is described in Section 1.) However, absorption through the skin does constitute a danger, and methanol should be prevented from coming in direct contact with skin.

Appropriate workplace hygiene measures should be adopted if methanol is handled constantly. Rooms in which methanol is stored or handled must be ventilated adequately. The TLV – TWA value (skin) is 200 ppm (262 mg/m^3), and the TLV – STEL value is 250 ppm (328 mg/m^3). The MAK value is 200 ppm (270 mg/m^3). Gas testing tubes can be used to measure the concentration in air. The peak limit should correspond to category II, 1: i.e., the MAK value may be exceeded by a maximum of 100 % for 30 min, four times per shift [146]. Respirators must be worn if substantially higher concentrations are present. Filter masks (filter A, identification color brown) can be used only for escape or life-saving purposes because they are exhausted very quickly. Respirators with a self-contained air supply and heavy-duty chemical protective clothing should be used for longer exposures to high methanol concentrations ($>$ 0.5 vol %).

1. Introduction

Methine dyes and polyene dyes are characterized by a chain of methine groups forming a system of conjugated double bonds. The methine chain in *polyene dyes* is even-numbered and the terminal groups do not affect the excitation of electrons in the dye. The most important group of polyene dyes, the carotenoids, bear aliphatic or alicyclic groups at the end of the methine chain, thus a very long conjugated chain is necessary to shift the excitation wavelength to the visible region spectrum. β-Carotene contains a chain of 22 methine groups. The dye absorbs at 450 and 478 nm.

Methine dyes are characterized by a chain of conjugated double bonds with an odd number of carbon atoms between the two terminal groups X and Y, which may be considered as being capable of charge exchange:

The substituents X and Y are groups of atoms, whereby one group acts as an electron acceptor and the other as an electron donor. Depending on the nature of the charge q, the dyes may be cationic, anionic, or neutral. Cationic methine dyes may be regarded as vinylogous amidinium salts:

1 2

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a16_487

Similarly, anionic methine dyes may be classified as vinylogous carboxylate ions,

and neutral methine dyes as vinylogous carbonamides:

Methine dyes have an extended system of conjugated double bonds. A large number of resonance structures may therefore be formulated, of which (**1**) and (**2**) are the most important, i.e., the electron density is lowest on the nitrogen atoms. In all the following formulae only one resonance structure is shown. To indicate that a π-electron system with many possible resonance structures is involved, the total charge of the molecule is given outside a square bracket.

The electron density distribution in the ground state is generally different from that in the excited state, which means that light absorption by the dye molecule results in a redistribution of the electrons, but the total charge remains constant. Thus, the electronically excited state of a neutral methine dye molecule can be described by a betaine structure. The transition to the betaine structure may be associated with a large shift of the absorption wavelength if the chromophore system is formed by addition of energy with ring opening. Thermochromism refers to excitation by heat, and photochromism to excitation by light.

In the following classification of methine dyes only nitrogen and oxygen are considered as charge-carrying terminal atoms, although other heteroatoms are possible. The charge-carrying terminal atoms may be joined directly to the methine chain, may be linked via an aromatic group to the methine chain, or may form part of a heterocyclic ring.

There are several types of *cationic methine dyes.* Polymethine dyes that do not contain a heteroatom and in which the carbon atom is positively-charged are derived from azulenes.

Streptocyanine dyes contain both charge-carrying atoms at the ends of the methine chain:

Aminoarylenamine dyes are obtained by insertion of an aryl ring:

If the second charge-carrying terminal atom is separated from the methine chain by an aryl group, then di- and triarylmethane dyes and their vinylogs are obtained (→ Triarylmethane and Diarylmethane Dyes, Chap. 6.):

In hemicyanine dyes one of the charge-carrying terminal atoms is a member of a heterocyclic ring. Since the second nitrogen atom is directly coupled to the methine chain, these are also enamine dyes:

The phenylogous hemicyanine dyes are obtained by inserting an aryl group between the second nitrogen atom and the methine chain of the hemicyanine dyes. These dyes are often termed styryl dyes since they mostly contain an ethylene group linked to a phenyl group:

Finally, if the second charge-carrying terminal atom is also a member of a heterocyclic ring, then cyanine dyes are obtained:

Carbinols are formed from cationic methine dyes by the action of alkalis. The hydroxyl group moves to the carbon atom with the lowest electron density. Carbinol ethers are similarly formed by reaction with alkoxides. If the dye contains a carboxyl group in a sterically favorable position, a lactone ring is formed under the action of alkalis with the elimination of water. All these carbinol derivatives are colorless compounds that are reconverted to the dyes by the action of protons.

Anionic methine dyes may be classified in a similar way. The simplest representative of the oxonols is the metal salt of glutaconaldehyde:

$$[O{=}CH{-}(CH{=}CH)_2{-}O]^-$$

The dioxytriphenylmethane dyes are phenylogous oxonols:

In the most important class of oxonol dyes both charge-carrying terminal atoms are bound to a ring system:

$$O{=}C{-}C{=}CH{-}(CH{=}CH)_n{-}C{=}C{-}O^-$$

Neutral methine dyes (neutrocyanine dyes) may be subdivided as follows. In enamineneutrocyanines the donor and acceptor groups are directly linked to the methine chain:

$$N{-}(CH{=}CH)_n{-}C{=}O \quad (\equiv N)$$

Aminoarylneutrocyanine dyes are obtained by inserting an aryl group between the amino group and the methine chain. Since the styrene structure is present, these dyes are also termed neutral styryl dyes:

Finally, the electron-donating nitrogen can be a member of a heterocyclic ring, both in open-chain neutrocyanines

$$N{-}C{=}(CH{-}CH)_n{=}C{-}C{=}O \quad (\equiv N)$$

and in cyclic neutrocyanines (also called merocyanines):

$$N{-}C{=}(CH{-}CH)_n{=}C{-}C{=}O$$

The merocyanines also include the quinophthalones

and the spiropyrans,

which undergo ring-opening on excitation by light to form hydroxyarylneutrocyanine dyes with the betaine structure.

The squaric acid dyes

and the carbonylhomologous croconic acid (i.e., 4,5-dihydroxy-4-cyclopentene-1,2,3-trione) dyes always exist in the betaine form.

The methine dyes may be subdivided further according to the number of methine groups that are neither part of an aromatic ring nor part of a heterocyclic ring. A differentiation is made between mono-, di-, and trimethine dyes, etc. The lowest vinylogs of dimethine dyes do not contain a methine chain; the two terminal systems are directly coupled to one another. These dyes are termed zeromethine dyes or apocyanine dyes.

One or more members of the methine chain may be replaced by nitrogen, which is indicated by the term "aza". Depending on the number of nitrogen atoms introduced, monoaza- or diazadimethine dyes, etc., can be obtained. In 1977, 2 CH groups in the chain have also been replaced by phosphorus or arsenic to give the corresponding phosphamethine or arsamethine dyes. A comprehensive systematic classification of polymethine dyes can be found in [9].

2. History

The first methine dye was discovered in 1856 by G. Williams and was named cyanine on account of its brilliant blue color. In 1863 A. W. v. Hofmann established that the lepidine fraction in crude tar quinoline is essential for the formation of cyanine. S. Hoogewerf and W. A. Van Dorp prepared cyanine from pure quinoline and lepidine. In the same year W. Spalteholz discovered the violet isocyanines, which were formed by an analogous reaction from quinoline and quinaldine. In 1904 A. Miethe and G. Book correctly identified isocyanines as quinoline rings joined in the 2- and 4-positions by a

methine group. In 1906 W. König then proposed the correct structural formula. In 1912 A. Kaufmann and E. Vonderwahl discovered pseudocyanine, in which two quinoline rings are coupled in the 2,2-position by a methine bridge. The structure of this dye was verified by O. Fischer and G. Scheibe in 1920.

The chemical industry became interested in cyanines after their application as sensitizers in photography became known. In 1920 W. H. Mills and F. M. Hamer showed that pinacyanol had the structure of a vinylhomologous pseudocyanine, and it was therefore one of the first trimethinecyanine dyes to be synthesized. Trimethinecyanines were first prepared in 1922 by W. König using orthoformates and heterocycles with methyl or methylene groups capable of undergoing condensation. L. G. S. Brooker performed detailed investigations into the suitability of these dyes as sensitizers in silver-based photography. In 1912 W. König reported the preparation of styryl dyes; an important dye of this series is pinaflavol, which was discovered in 1920. Quinoline Yellow, discovered by E. Jacobson in 1882, was probably the first neutrocyanine; its structure, a zeromethineneutrocyanine, was established later. The first oxonol dye was Pyrazolone Yellow, discovered by E. Besthorn and L. Knorr in 1887.

With the development of cellulose acetate fibers, methine dyes became important for textile dyeing. Astraphloxin, the trimethine dye formed from 1,3,3-trimethyl-2-methyleneindoline and sodium formate, dyes cellulose acetate a brilliant pink. Progress was achieved in 1936 with the more lightfast styryl dyes synthesized from aminobenzaldehydes and 1,3,3-trimethyl-2-methyleneindoline. In 1938 dimethinecyanines were synthesized from the same base and indolaldehydes; and enamine dyes were synthesized from 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde [systematic name: (1,3-dihydro-1,3,3-trimethyl-2 *H*-indol-2-ylidene)acetaldehyde] and aromatic amines. The Astrazon range for cellulose acetate printing, based on the above dyes, was introduced commerically in 1938 by IG Farben.

The importance of methine dyes for textile dyeing grew with the development of polyacrylonitrile fibers. It was found that a whole range of methine dyes could dye these fibers brilliantly and were extremely lightfast. Leading dye manufacturers throughout the world were subsequently engaged in intensive research and development programs. The diazadimethine-hemicyanine dyes (Geigy 1954), prepared by oxidative coupling of heterocyclic hydrazones with aromatic amines and described in the same year by S. Hünig became particularly important. Geigy produced these dyes by coupling of diazotized heterocyclic amines with aromatic amines and subsequent quaternization.

The apocyanine dyes synthesized from naphtholactam and aromatic amines (Bayer 1961) also became industrially important. Neutrocyanine dyes synthesized from 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde and alkyl cyanoacetates dye polyamide fibers in brilliant, lightfast shades (Bayer 1958). Neutral styryl dyes synthesized from aminobenzaldehydes and malononitrile were introduced commercially from 1960 onwards; they dye polyester fibers in brilliant yellow shades.

The range of dyes for dyeing paper (previously diphenylmethane, triphenylmethane, and rhodamine dyes) has been supplemented by methine dyes with yellow, orange, and red shades. Cationic neutrocyanine dyes synthesized from aminobenzaldehydes and cationic alkyl cyanoacetates (Bayer 1977); dimethine dyes synthesized from aminobenzaldehydes and quaternized γ-picoline (BASF, Bayer 1979); and enamine dyes synthesized from 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde and aromatic diamines and trimerized by cyanuric chloride (Ciba-Geigy 1980) have become important.

Brilliant blue neutrocyanine dyes are obtained by reacting aminobenzaldehydes with 3-dicyanomethylene-benzothiophene dioxide (Sandoz 1978). A brilliant red, classified as a cyclic neutrocyanine dye and having a bislactone structure, was introduced commercially by ICI in 1984.

Methine dyes have also proved valuable in research. They have been used to investigate the relationship between chemical structure and light absorption, the reactivity of organic compounds, the transmission of light energy, and the formation of associates.

Photochromic compounds are obtained by reacting 1,3,3-trimethyl-2-methyleneindoline with derivatives of 2-hydroxybenzaldehyde (Fischer and Hirshberg 1952). They have been used experimentally in optical data storage, but

the fulgides, derivatives of succinic anhydride discovered by HELLER and DARCY in 1981, proved to be more suitable. Polymethine dyes absorbing in the IR region and betaines formed from squaric acid and aromatic amines or thiopyrylium salts are used for nonerasable optical data storage (Philips 1983) (→ Information Storage Materials, Chap. 2.4.6.).

3. Preparation

Reactive methyl, methylene, and carbonyl groups and their derivatives are the most important groups for constructing the methine chains. Heterocyclic methylene compounds, in particular 1,3,3-trimethyl-2-methyleneindoline, as well as aromatic amines can be converted to the corresponding aldehydes by means of the Vilsmeier reaction. The Vilsmeier reagent is the product formed by reacting phosphorus oxychloride with dimethylformamide. Instead of phosphorus oxychloride, thionyl chloride or phosgene may also be used:

This heterocyclic α,β-unsaturated aldehyde reacts in glacial acetic acid with primary aromatic amines to form hemicyanine dyes, and with heterocyclic compounds containing activated methyl or methylene groups to form trimethinecyanines. Reaction with tertiary aromatic amines to form styryl dyes requires more aggressive conditions; phosphorus oxychloride is a suitable condensing agent. Styryl dyes can be prepared under milder conditions if aminoarylaldehydes are formed by the Vilsmeier reaction and then reacted with heterocyclic compounds containing a methyl or methylene group capable of undergoing condensation. Glacial acetic acid is a suitable condensing agent. In many cases it is not necessary to hydrolyze the intermediate formed in the Vilsmeier reaction, it can be condensed further to form the methine dyes. This one-pot reaction has economic advantages.

Preparation of styryl dyes by condensation of aminobenzaldehydes with 1,3,3-trimethyl-2-methyleneindoline in a paddle wheel dryer with addition of inorganic or organic acids has ecological advantages. Conversion is quantitative, with the result that a directly marketable dye is produced without any wastewater.

Suitable starting compounds for preparing symmetrical trimethinecyanines are formic acid derivatives (e.g., sodium formate, orthoformates, or chloroform). Methine dyes with longer chains are obtained by reaction with malonaldehyde, glutaconaldehyde, or their derivatives.

Monoazamethine dyes are prepared by using the corresponding nitroso compounds instead of the formyl compounds. Diazamethine dyes are prepared from heterocyclic azo dyes that are obtained by diazotizing heterocyclic amines and coupling with aromatic or heterocyclic coupling components. Diazadimethine dyes are obtained by quaternization at the heterocyclic nitrogen atom. Preparation of these dyes can be simplified by dissolving the heterocyclic amines with the aromatic or heterocyclic coupling components in an organic acid and reacting with sodium nitrite. The heterocyclic azo dyes are formed in a simultaneous diazotization and coupling reaction. If this solution is reacted with quaternization agents, solutions of diazadimethine dyes suitable for use in dyeing are obtained without the formation of wastewater.

Also in the case of diazadimethine dyes, total charge equalization (mesomerism) between the terminal groups is possible. This group of dyes is thus clearly distinguished from the cationic azo dyes (→Azo Dyes, Chap. 5.).

The Knoevenagel condensation of aromatic or heterocyclic aldehydes with enolate forming compounds (e.g., malononitrile, alkyl cyanoacetates, pyrazolones) is used industrially to prepare neutrocyanine dyes. If the aromatic aldehydes bear a hydroxy group in the 2-position, ring closure with the formation of coumarin takes place after condensation, and strongly fluorescent dyes are obtained.

The reaction products are generally sufficiently pure for dyeing. However, the dyes usually need to be further purified if they are to be used as sensitizers, chromatographic separation

on aluminum oxide is often necessary. The degree of purity must be checked by chromatographic analysis and absorption spectroscopy. As a more rigorous check, the dye is added to a silver halide emulsion which is then used to coat paper or a film. The sensitivity of the photographic layers is measured as a function of wavelength and light intensity. Very small amounts of impurities can be detected by comparison with standard photographs.

4. Properties

Polymethine dyes are generally stable to reducing agents but are decolorized irreversibly by oxidizing agents. Decolorization by acids is reversible; here a proton becomes attached to the free electron pair of the donor group. In alkaline media a carbinol is formed, OH^- being attached to the carbon atom of lowest electron density in the conjugated system, generally adjacent to the charge-carrying terminal atom. Styryl dyes with aromatic hydroxyl groups ortho to the methine chain form colorless spiro compounds with alkalis, accompanied by ring closure. In acidic media the methine dyes are reformed from the carbinol derivatives. Compounds of this type are important in the production of colorless copying papers.

In many cases the carbinols formed are unstable and decompose with cleavage of the methine chain. In streptocyanines the immonium group is particularly easily hydrolyzed to give corresponding aldehyde or ketone.

The stability of polymethine dyes decreases with an increase in the number of methine groups. Solutions are less stable than the pure substances. Mono- and trimethinecyanines are generally stable for several months in methanol, whereas solutions of undecamethine cyanines become unusable even after a few hours.

Lightfastness. Lightfast methine dyes for dyeing polyacrylonitrile fibers or plastics are the zero-, mono-, di-, and trimethine dyes. Lightfastness is frequently improved by introducing aza groups in the methine chain so that many diazadimethine dyes are very lightfast. Surprisingly, many tetraazapentamethine dyes are still lightfast when applied to polyacrylonitrile.

Light Absorption. Short-chain methine dyes absorb mainly in the shortwave region of the visible spectrum and are yellow, but some short-chain methine dyes with polynuclear heterocycles as terminal groups absorb in the longwave region of the spectrum. Zeromethine dyes synthesized from naphtholactam and aromatic amines and used to dye polyacrylonitrile are therefore blue. Extension of the methine chain by one vinyl group results in a 100 – 120 nm-bathochromic shift of the absorption maximum. Chain extension can lead to light absorption in the IR region (1500 nm).

All methine dyes have a high absorption intensity. The molar extinction coefficient reaches 30 000 even for the simplest dyes, and increases up to 250 000 for the longer-chain dyes. The absorption curve is generally unsymmetrical; the rise on the longwave side is steeper, while a second band appears on the shortwave side of the maximum. The extinction coefficient is greatest with symmetrical molecules. Steric hindrance interferes with the planar orientation of the conjugated systen. The half band width of the longwave band is thus increased and the extinction coefficient at the absorption maximum is generally reduced.

5. Uses

In the textile industry polymethine dyes are mostly used to dye polyacrylonitrile. The fibers are dyed in all processing stages such as loose stock, tow, yarn, and fabric. Dye mixtures are used to dye black. Mixtures of hydrazone, azo, diazacyanine, and naphtholactam dyes are of practical importance [10]. Styryl, triphenylmethane [11], and oxazine dyes [12] are also used. In order to reduce dust formation, liquid formulations are employed increasingly [13]. In the case of styryl dyes the preparation can be combined with the formation of concentrated dye solutions in a single stage [14]. Porous polyacrylonitrile fibers (Dunova, Bayer) are also dyed with polycationic dyes [15]. Level dyeing on polyacrylonitrile is obtained with low-molecular mass migrating dyes. Hydrazone, diazacyanine, and oxazine dyes are used [16]. The leveling ability of commercial polyacrylonitrile dyes can be improved by adding migrating dyes [17]. In the dry spinning process poly-

acrylonitrile is spun from an organic solvent, preferably dimethylformamide. Cationic dyes are added to these solutions to produce spun-dyed fibers. Bleeding into the drawing bath can be prevented by using special anions, e.g., nitrates [18], tetrafluoroborates [19], iodides [20], and rhodanides [21]. Styryl dye solutions suitable for spin dyeing can be prepared by reacting 4-aminobenzaldehydes with 1,3,3-trimethyl-2-methyleneindoline and toluene-4-sulfonic acid in dimethylformamide [22]. Concentrated solutions of cationic methine dyes are used on a large scale to dye polyacrylonitrile fibers during spinning in the gel state.

The dye formulations (all registered trademarks) of the most important producers of polyacrylonitrile dyes are as follows:

Aizencathilon	Hodogaya
Asahiacryl	Asahi
Astrazon	Bayer
Atacryl	Atlantic
Basacryl	BASF
Diacryl	Mitsubishi
Kayacryl	Kayaku Nippon
Maxilon	Ciba-Geigy
Nichilon	Nissei Kasei
Panacryl	Holliday
Sandocryl	Sandoz
Sumiacryl	Sumitomo
Synacril	ICI
Yoracryl	Yorkshire Chem.
Viocryl	Viochrom
Yation	Yamada

A whole range of methine dyes also dye acid-modified polyester fibers very lightfast. Black-dyeing can again be produced with dye mixtures. The same types of dye are used as for polyacrylonitrile [23]. Acid-modified polyamide is dyed using hemicyanine dyes to give lightfast yellow shades. Methine dyes containing triazine groups are used to dye paper [24].

Neutrocyanine dyes are suitable for dyeing polyamide and polyester fibers as well as for dyeing thermoplasts such as polystyrene and poly-(methyl methacrylate). On account of their low molecular mass, aminoarylneutrocyanines are used for sublimation thermotransfer printing on polyester fabrics, and especially as the yellow component for reproducing electronically recorded color photographs [25].

Some monomethinecyanines and their aza derivatives are used as optical brighteners, because they are colorless and fluoresce strongly. Some methine dyes are used for histological staining. Various cyanine dyes, e.g., benzothiazolepentamethinecyanine, act as antifilarial agents and anthelmintics, although colorless substances are preferred. In analytical chemistry anionic cyanines are also used to detect alkaline earth metals. Polymethine dyes are particularly important as spectral (optical) sensitizers in photography (→Photography).

6. Economic Aspects

In 1988, 26 000 t of cationic dyes with a value of 560×10^6 DM ($\$310\times10^6$) were required worldwide to dye 2.5×10^6 t of acrylic fibers. A polyacrylonitrile fiber consumption of 2.75×10^6 t is anticipated for 1993; the dye requirement will then amount to 27 000 t with a value of 610×10^6 DM ($\$400\times10^6$). The most important manufacturers of these dyes are Bayer and Ciba-Geigy. The requirement may be broken down according to dye shades: yellow 7300 t, orange 1300 t, red 5300 t, violet 1000 t, blue 7000 t, green 1000 t, black 3100 t. Cationic azo dyes represent a significant proportion of red dyes. Malachite Green continues to be an important dye for green and black shades. The remainder is covered by the methine dyes.

7. Cationic Methine Dyes

The most important group of methine dyes are the cationic compounds, especially those in which nitrogen is the cationic charge carrier.

7.1. Streptocyanine Dyes

In streptocyanine dyes both ends of the methine chain are joined directly to nitrogen atoms, a double enamine structure is thus present. The dyes are extremely susceptible to hydrolysis, particularly if they contain secondary nitrogen atoms. Stable dyes are obtained if the nitrogen is part of a heterocyclic ring system.

7.1.1. Trimethinestreptocyanine Dyes

Streptocyanine dyes with three methine groups have a coloring strength sufficient for practical

use if the nitrogen is part of a ring and if the aromatic ring bears an alkoxy group in the 4-position relative to the nitrogen atom.

[39922-76-4]

Streptocyanine dyes are brilliant yellow dyes that dye polyacrylonitrile and acid-modified polyamide fibers with outstanding lightfastness [26]. Unsymmetrical trimethinestreptocyanine dyes are obtained by reaction of partially hydrogenated heterocycles with propyn-1-al and addition of the second heterocyclic component at the triple bond [27].

7.1.2. Pentamethinestreptocyanine Dyes and Higher Vinylogs

The pentamethinestreptocyanine dyes are formed by reaction of bromine cyanide, chlorine cyanide, or 2,4-dinitrochlorobenzene with pyridine and cleavage of the resultant compounds with primary or secondary amines. The tetraacetal of glutaconaldehyde is also used to form the methine chain [28]. The dyes can be used to dye paper. The greenish-yellow dyes prepared by reaction with *N*-ethyl- or *N*-methylaniline [29] were marketed as Astra Yellow G and R, respectively:

[13984-07-1]

Pentamethinestreptocyanine dyes synthesized from primary aromatic amines undergo ring closure on heating with the elimination of aniline, to form the colorless phenylpyridinium chloride. They are used as heat-bleachable antihalo dyes in photothermographic processes [30]. Ring closure involving both nitrogen atoms produces a considerable bathochromic shift. Rosol Scarlet is obtained with 2-methyl-2,3-dihydroindole as the amine component [31].

To prepare streptocyanine dyes containing an acyloxy group in the methine chain, vinylogs of furfural are used as starting material; the furan ring is cleaved with hydrochloric acid [32].

[126795-20-8]

Streptocyanine dyes are used to synthesize long-chain cyanine dyes.

7.1.3. Aminoarylenamine Dyes

Aminoarylenamine dyes are phenylogous streptocyanines, and are formed by condensing aromatic aminoaldehydes with aromatic amines. If the aromatic amine bears a substituent with electron-donor properties, the enamine dyes are sufficiently stable to be adsorbed on polyacrylonitrile without hydrolytic decomposition. The yellow dye

[85291-90-3]

is very lightfast [33]. The dye bases of these compounds are colorless or only slightly colored, and are used in carbonless copying paper. Solutions of the dye bases are encapsulated in microcapsules made of gelatin or polycondensation products and coated onto paper. If this is brought into contact with paper bearing a coating of a compound that acts as an electron acceptor (e.g., attapulgite) and the capsules are destroyed by pressure, the color bases are protonated to the enamine dyes, thereby producing yellow or orange dyeings of high intensity. The following compound

is particularly suitable in this respect and is also used for the preparation of black copying mixtures [34].

The color bases can also be sublimated image wise from a transfer ribbon onto an acid-developing receiver sheet. They then form the yellow component in color transfer prints [35].

7.2. Hemicyanine Dyes

In hemicyanine dyes one of the charge-carrying terminal atoms of the methine chain forms part of a heterocyclic ring. The lowest vinylogous hemicyanine dyes (cyclomethine dyes) do not contain a methine chain and the donor and acceptor groups are in the same ring system.

7.2.1. Cyclomethine Dyes

Cyclomethine dyes can be prepared by condensing N-heterocyclic carbonyl compounds with secondary amines. Intensely colored products are obtained by condensing 3-phenylpyrazoline with compounds such as *N*-ethylnaphtholactam:

[34708-09-3]

This compound dyes polyacrylonitrile a brilliant, lightfast yellow. Orange-red dyes are obtained by condensing acridone with secondary amines [36].

7.2.2. Dimethinehemicyanine Dyes

Dimethinehemicyanine dyes and their aza analogues are important for dyeing polyacrylonitrile. Most of the dyes that color polyacrylonitrile in greenish to reddish-yellow shades belong to this class.

Enamine Dyes. Enamine dyes are obtained by condensation of heterocyclic methylene-ω-aldehydes with aromatic amines in an acid medium. Technically important dyes contain 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde as aldehyde component [37]. *C.I. Basic Yellow 11*, the condensation product formed with 2,4-dimethoxyaniline, is of particular importance:

[4208-80-4]

This compound dyes polyacrylonitrile a lightfast, brilliant, greenish-yellow shade. In 1989, 900 t of Basic Yellow 11 were produced worldwide.

Preparation. A solution of 124 kg of 2,4-dimethoxyaniline in 1000 kg of 20 % sulfuric acid is added to a solution of 158 kg of 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde in 820 kg of 20 % sulfuric acid. The mixture is stirred at room temperature until the formation of the dye is complete. The yellow crystals are pressed, dissolved, and allowed to crystallize from water, and the purified dye is dried. A yield of 217 kg is obtained, corresponding to 720 kg commercial grade.

Commercial Products. C.I. Basic Yellow 11 is included in practically all important dye ranges for dyeing polyacrylonitrile fibers. Commercial products include Astrazon Yellow 3GL, Maxilon Yellow 3GL, Basacryl Yellow X-3GL, Atacryl Yellow 4G, Yoracryl Yellow 4G, Aizencathilon Yellow 3GLH, Asahiacryl Yellow 3GL, Kayacryl Yellow 2GL, Sumiacryl Yellow 3G, Yation Yellow 3GS, Viocryl Yellow 3GS.

C.I. Basic Yellow 13 is obtained in a similar manner to Basic Yellow 11 by condensation of 4-anisidine with the ω-aldehyde. It dyes polyacrylonitrile a greener shade. In 1989, 150 t of this dye were produced worldwide.

Commercial Products. Astrazon Yellow 8GL, Basacryl Yellow X-4GL, Maxilon Brilliant Yellow 5GL, Panacryl Yellow 8GL, Sandocryl Brilliant Yellow B-6GL, Sumiacryl Brilliant Yellow 5G, Synacril Fast Yellow 8G, Nichilon Yellow 5GL.

The following amine components have also been proposed for condensation with methyleneindoline-ω-aldehydes: 4-aminophenylglycolether [38], 4-aminoacetanilide

[39], and 2-(4-aminophenyl)benzoxazole, -benzothiazole, -benzimidazole and -benzotriazole [40]. Diamines react with methyleneindoline-ω-aldehydes in a molar ratio of 2 : 1 to form yellow dyes suitable for dyeing paper. Suitable components are bis-4-aminophenylether, 4,4'-diaminodiphenylsulfone [41], or the 4-aminophthalic anhydride dimerized by aliphatic diamines [42]. Cyanuric chloride can be reacted twice or three times with 4-aminoacetanilide and the acetyl group can then be split off by acid hydrolysis. Reaction of the product with an equivalent amount of 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde yields yellow dyes with a high affinity for paper [43]. Commercial products include Duasyn Direct Yellow KG liq. (Hoechst) and Pergasol Yellow FG liq. (Ciba-Geigy). The tetrafluoroborates of these dyes are suitable for spin dyeing polyacrylonitrile [44].

The low molecular mass bases of enamine dyes can be sublimed by means of a thermohead from a transfer ribbon onto a receiving material and serve as yellow components for producing color copies in sublimation transfer printing [45].

Vinylogous enamine dyes are obtained by reaction of aromatic amines with mucochloric acid (2,3-dichloro-4-oxo-2-butanoic acid), followed by condensation with quaternary quinaldine. After methylation of the enamine nitrogen with dimethylsulfate a dye is obtained that dyes bleached sulfite pulp red [46]:

Enhydrazine dyes, synthesized from methyleneindoline-ω-aldehydes and the monoalkyl hydrazones of aromatic aldehydes, fluoresce in solution and on the fiber [47].

[56190-67-1]

Dyes prepared by condensation of methyleneindoline-ω-aldehydes with cyclic amino compounds have high lightfastness and resistance to hydrolysis [48].

C.I. Basic Yellow 21 is synthesized from 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde and 2-methyl-2,3-dihydroindoline. It dyes polyacrylonitrile in brilliant, greenish-yellow shades and is very lightfast:

[6359-50-8]

Commercial Products. Astrazon Yellow 7GLL, Maxilon Yellow 6GL, Panacryl Yellow 7GLL, Diacryl Brilliant Yellow 7GL-N, Aizencathilon Yellow 7G-DP, Estrol Yellow 7GL-SD. In 1989 worldwide production was 400 t.

The shade is changed to golden-yellow by introducing a phenylazo group into C.I. Basic Yellow 21. Alkoxy substitution of the cyclic amine component in the 4-position to the nitrogen increases the coloring strength considerably [49]. Dyes of this type include Astrazon Yellow 8GSL and Sevron Yellow 8GMF:

[27326-17-6]

Suitable N-heterocycles also include tetrahydrobenzoxazine [50] and tetrahydroquinoxaline. The latter produces a marked bathochromic shift. Sevron Yellow CP dyes polyacrylonitrile a neutral yellow shade [51]:

[28766-22-5]

A brilliant greenish-yellow dye is obtained by condensing methyleneindoline-ω-aldehydes with 3-phenylpyrazoline [52]:

[31612-53-0]

If methyleneindoline-ω-aldehydes are condensed with cyclic amines substituted by an amino group in the aromatic ring, dyes are obtained that can be dimerized either by reaction with cyanuric chloride in a molar ratio of 2 : 1 or with phosgene. On account of their high substantivity these dyes are suitable for dyeing bleached sulfite pulp [53].

Instead of methyleneindoline-ω-aldehydes, the corresponding compounds derived from 2-methyl-benzothiazole have also been used. The resultant dyes are taken up by polyacrylonitrile quickly and are extremely lightfast [54].

Hydrazone Dyes. If the diazonium salts of aromatic amines are coupled with the methylene derivatives of N-heterocycles, hydrazone dyes (i.e., the monoaza derivatives of the enamine dyes) are obtained. Paper and leather can be dyed in yellow to red shades with these dyes [55]. They are moderately lightfast on polyacrylonitrile. If the diazo components contain substituents in the 2-position relative to the amino group that can form a hydrogen bond (e.g., 2-nitroaniline [56] or 1-aminoanthraquinone [57]), lightfastness is improved considerably:

[27564-03-0]

Lightfastness can also be improved by a hydrogen-bond-forming substituent (e.g., a cyano group) in the coupling component [58]:

Such dye salts are converted to azo bases by alkali. Alkylating agents attack the nitrogen atom of the azo bond, forming alkylarylhydrazone dyes which dye polyacrylonitrile in lightfast, yellow to orange shades [59].

Diazotization, coupling, and methylation may be combined in a one-pot process by dissolving the aromatic amine and the heterocyclic methylene base in an organic acid and effecting the simultaneous diazotization and coupling by addition of sodium nitrite. The dye base is released by addition of alkali and is methylated with dimethyl sulfate to form the alkylarylhydrazone dye [60].

Preparation. 123 kg of *p*-anisidine is added to a mixture of 400 kg of water and 120 kg of glacial acetic acid under a nitrogen atmosphere. The reaction mixture is then cooled to 10 °C and 173 kg of 1,3,3-trimethyl-2-methyleneindoline added. A solution of 70 kg of sodium nitrite in 90 kg of water is added within 1 h at 10 °C. The temperature is then allowed to rise to 15 °C within 1 h and to 19 °C within the next 50 min. Cooling is then stopped. The suspension heats up as a result of the exothermic reaction, and after 20–30 min a temperature of 30–35 °C is reached. Beginning at 33 °C 50 kg of chlorobenzene is added, whereby the temperature rises to 61–62 °C. Conversion is complete after 30 min and the content of 1,3,3-trimethyl-2-methyleneindoline and *p*-anisidine is less than 0.1 %. Chlorobenzene (450 kg) is now added to the suspension and heated to 80 °C, the stirrer is switched off, and the aqueous phase is separated. The organic phase is cooled to 40 °C, 6 kg of magnesium oxide is added, 134 kg of dimethyl sulfate is added dropwise at 40 °C within 1 h followed by 18 kg of water within the next hour. The reaction mixture is then stirred for 6 h at 40 °C, a further 20 kg of dimethyl sulfate being added after 2 h. At this stage the content of unquaternized dye in the suspension is less than 0.03 %. After adding 200 L of water the pH value is adjusted to 2.5 with concentrated hydrochloric acid and the solvent is distilled off with steam. 1100 L of dye solution remain, which is salted out with 55 kg of sodium chloride, if necessary after clarification with activated charcoal at 50 °C. The dye suspension is then stirred for several hours at room temperature, and the dye is separated in a filter press, washed with 750 L of 5 % sodium

chloride solution, and dried. A yield of 440 kg is obtained, corresponding to 2000 kg commercial grade. Basic Yellow 28 dyes polyacrylonitrile golden yellow with very good lightfastness:

[*36528-10-6*]

Industrially important hydrazone dyes are:

1) Basic Yellow 28 (1988 production 3300 t worldwide): Astrazon Golden Yellow GL, Basacryl Golden Yellow X-GFL, Diacryl Golden Yellow GLN, Kayacryl Golden Yellow GL, Atacryl Yellow 2RL, Estrol Golden Yellow E-GL, Maxilon Golden Yellow GL, Panacryl Golden Yellow GL, Yation Yellow GLS.
2) Basic Yellow 29 [*38151-74-5*] (1989 production 200 t worldwide): Astrazon Yellow GRL, Atacryl Yellow GRL, Yation Yellow HS, Yracryl Yellow 2GL.
3) Basic Yellow 51 [*55850-01-6*] (1988 production 150 t worldwide): Astrazon Yellow 5 GL, Basacryl Yellow X-2GLN, Diacryl Yellow 3GN, Sumiacryl Yellow N-4G.
4) Basic Yellow 66: Diacryl Yellow 2GL-N.
5) Basic Yellow 70: Diacryl Yellow 3RL-F.
6) Basic Yellow 51, being a nitrate, is particularly suitable for preparing gravure and flexographic inks, and is marketed under the name Flexo Yellow 118 (BASF) [61].

Alkylation to form the cationic hydrazone dyes can also take place continuously in a two-phase system [62]. Alkylation in a purely aqueous medium is problematic on account of the hydrolysis of the dimethyl sulfate. Arylsulfonates are used in this case [63]. If special conditions are employed, the reaction can also be carried out with dimethyl sulfate using very small amounts of water [64] with the addition of urea [65] or sodium or magnesium sulfate [66].

Hydrazone dyes with an additional external cationic charge are suitable for use in writing inks, stamp pad inks and ball-point pen pastes [67]. Hydrazone dyes with acylamino groups can be hydrolyzed to compounds with a free amino group which dye polyacrylonitrile in red shades [68]. These compounds can be dimerized by reaction with phosgene, dicarboxylic acid chlorides, or cyanuric chloride in a molar ratio of 2 : 1. The dimerized compounds have a high affinity for cellulose and are suitable for dyeing bleached sulfite pulp [69]. The compounds with a free amino group can also be diazotized and reacted with aromatic or heterocyclic coupling components to form azohydrazone dyes [70].

In addition to the methyleneindolines, 4-methylene derivatives of 1,3-dialkylpyrimidin-2-one have also been used to prepare hydrazone dyes [59], [71]:

[*73297-08-2*]

A dye of this series is Basic Yellow 49, Basacryl Yellow X-RL.

Violet and blue hydrazone dyes are obtained with a methylene base derived from naphtholactam [72]:

Heterocyclically substituted acetic acids (e.g., benzothiazolyl, benzimidazolyl [73], and pyrimidyl acetic acids [74]) are also suitable as coupling components for preparing cationic hydrazone dyes. In these compounds the methyl group in the 2-position is additionally activated. The carboxyl group is split off after coupling and the azo base is methylated.

Alkylarylhydrazone dyes can also be produced by reacting suitable heterocyclic aldehydes with arylhydrazines. Subsequent alkylation of the heterocyclic nitrogen atom produces dyes that dye polyacrylonitrile extremely lightfast [75]:

[42476-20-0]

The hydrazone dyes of the pyridine, quinoline, and acridine series can be prepared by this route. Hydrazone dyes that are derived from pyridine exhibit a particularly good leveling ability when dyeing polyacrylonitrile [76]. Dyes of this series include Maxilon Yellow M-3RL and Maxilon Yellow M-4GL.

Hydrazone dyes of the pyridine series can be alkylated in an aqueous medium [77]. Pyridinealdehydephenylhydrazones are also obtained by reaction of aminomethylpyridine with a ketone, rearrangement to the azomethine, and subsequent reaction with phenylhydrazine [78].

If N-amino nitrogen heterocycles are used as the hydrazine component, cyclic hydrazone dyes are obtained whose absorption maximum is shifted bathochromically with respect to the open-chain hydrazone dyes [79]. The dye shown below dyes polyacrylonitrile fibers a clear bluish-red shade:

[72828-74-1]

Cyclic hydrazone dyes can also be prepared by intramolecular quaternization if diazo components are used that contain a leaving group in a sterically favorable position. The azo base formed from 2-(2-bromoethoxy)aniline closes the dihydrobenzoxazine ring with the elimination of a bromide ion. It dyes polyacrylonitrile a golden-yellow shade [80].

[69563-60-6]

Triazene Dyes (Diazadimethinehemicyanine dyes). If diazonium salts of N-heterocyclic amines are coupled to N-alkylanilines, e.g., diazotized 2-amino-6-methoxybenzothiazole to *N*-methyl-4-nitroaniline, a triazene is obtained. A cationic triazene dye is formed by subsequent N-alkylation, and dyes polyacrylonitrile a very lightfast yellow shade [81].

[14970-38-8]

Dyes from this range include Maxilon Yellow 4GL and 2RL. Worldwide production in Japan in 1989 was 200 t. Using 2-amino-5-dimethylamino-1,3,4-thiadiazole as diazo component and *N*-methylaniline as coupling component, a triazene dye is obtained that dyes polyacrylonitrile yellow and has a very good migration ability [82].

Of the enamine and hydrazone dyes, those with donor groups in the aryl system are particularly lightfast, whereas the lightfastness is reduced on the introduction of nitro groups. In contrast, triazene dyes with a nitro group attached to the aryl group are substantially more lightfast than those with a methoxy group attached to the aryl group.

Triazene dyes in which the terminal nitrogen atom is cyclically bound are obtained by coupling heterocyclic diazonium salts with partially hydrogenated N-heterocycles. In the following example alkylation was subsequently performed with ethylene oxide [83]:

7.2.3. Higher Vinylogs of Hemicyanine Dyes

Streptocyanine dyes are semihydrolyzed under mild conditions to give ω-aminopolyenealdehydes. If these aldehydes are condensed with heterocyclic quaternary salts containing a reactive methyl group, the higher vinylogous hemicyanine dyes are obtained. Trimethinestreptocyanines yield tetramethinehemicyanine dyes, while pentamethinestreptocyanines yield hexamethinehemicyanine dyes [84], e.g.,:

These dyes are used to sensitize photographic emulsions.

7.3. Phenylogous Hemicyanine Dyes

Phenylogous hemicyanine dyes are obtained by introducing a phenyl group between the charge-carrying nitrogen atom and the remaining dye system. The zeromethine (apocyanine) dyes are thus derived from the cyclomethine dyes. The styryl dyes are derived from the dimethinehemicyanine dyes by introducing a phenyl group between the charge-carrying nitrogen atom and the methine chain.

7.3.1. Zeromethine (Apocyanine) Dyes

Some representatives of the apocyanine dyes have been known for a long time, e.g., thioflavine T [*2390-54-7*]:

This dye is obtained by heating *p*-toluidine with sulfur and subsequent alkylation with methyl or ethyl sulfate. The dye colors silk and tanned cotton a greenish-yellow shade. Thioflavine S [*1326-12-1*] is obtained by sulfonation [85].

Apocyanine dyes of the acridine series are obtained by reacting acridinium iodide [86] or acridinium chloride [87] with tertiary aromatic amines. The dyes can also be obtained by ipso-substitution of acridinium iodide with 4-haloarylamines in dimethyl sulfoxide at room temperature [88].

The conversion of 2-methylbenzothiazole according to the Vilsmeier reaction leads to benzothiazolylmalonaldehyde. By condensation with 3-amino-*N*,*N*-dimethylaniline and subsequent methylation with dimethyl sulfate, a cationic dye is obtained that dyes paper a clear reddish-yellow shade:

[*69157-68-2*]

This is a styryl dye whose dimethine chain has been incorporated into a quinoline ring system and is therefore an apocyanine dye. The reaction can also be applied to 2-methyl-benzoxazole, 2,3,3-trimethylindolenine, or quinaldine [89].

The most important method for preparing apocyanine dyes is the reaction of N-heterocycles containing 2- or 4-carbonyl groups with secondary or tertiary aromatic amines in the presence of dehydrating agents (e.g., phosphorus oxychloride or tin tetrachloride).

Naphtholactam is a particularly important condensation component for preparing apocyanine dyes. In 1989 ca. 400 t of naphtholactam dyes were produced worldwide. At first only the dyes unsubstituted at the lactam nitrogen were prepared and recommended for dyeing tanned

cotton and wool [90]. However, it was later found that the N-alkyl derivatives dye polyacrylonitrile in very lightfast violet and blue shades:

[35114-09-1]

The dyes are synthesized either from N-alkylnaphtholactams, obtained by intramolecular Friedel–Crafts reaction of the 1-alkylnaphthylamine carboxylic acid chlorides, or by subsequent alkylation of the dye bases obtained by condensation of naphtholactam with aromatic amines [91].

Secondary aromatic amines, in particular those that also bear a substituent in the 2-position to the amino group, condense with N-alkylnaphtholactams to form dyes that are particularly lightfast on polyacrylonitrile [92]. A marked bathochromic shift occurs if the aminoaryl nitrogen atom is part of a heterocyclic ring. By condensation of *N*-ethylnaphtholactam with 1-phenyl-3,5,5-trimethylpyrazoline a dye is obtained that dyes polyacrylonitrile a lightfast blue shade [93]:

[40496-35-3]

Particularly lightfast dyes are obtained if 1-alkyl derivatives of 2,2,4-trimethyltetrahydroquinoline are used as amine components [94]:

This dye colors polyacrylonitrile a clear blue shade.

Commercial Products. Astrazon Blue 5RL, FRR, F2RL, Diacryl Brilliant Blue H2RN, Diacryl Supra Brilliant Blue HBL, and Maxilon Blue TRL.

N-Alkylnaphtholactam can be condensed with formaldehyde to form a dinaphthylmethane derivative and then reacted with aromatic amines or indole derivatives. These dyes are suitable for spin dyeing polyacrylonitrile and for dyeing paper [95]. The dyes with an unsubstituted lactam nitrogen atom can be converted into dye bases and used in this form for sublimation transfer printing on polyacrylonitrile fabrics [96]. Use of the carbinols of naphtholactam dyes in heat- or pressure-sensitive copying or recording materials has been proposed [97]. If the lactam nitrogen bears a carbonamidoethyl group as substituent, intramolecular lactam ring closure occurs under the action of alkali. These compounds can also be used as color formers [98].

Dye bases of apocyanine dyes derived from pyridine which is unsubstituted on the nitrogen are color formers for heat- or pressure-sensitive copying paper and develop into yellow to orange shades [99]:

[84754-34-7]

A commercial product of this range is React Yellow (BASF).

Dye bases of apocyanine dyes are also used as organic photoconductors in electrophotography [100].

7.3.2. Phenylogous Dimethinehemicyanine Dyes

These dyes are used widely in photography and textile dyeing. The diazadimethinehemicyanine dyes are particularly important in the textile sector.

Styryl Dyes. Styryl dyes are produced by condensation of 4-aminobenzaldehydes with N-heterocycles bearing an activated methyl group

in the 2- or 4-position. The starting components are usually briefly heated in glacial acetic acid. The aminoaldehydes can also be condensed with quaternary heterocyclic salts in the presence of basic catalysts such as piperidine, diethylamine, or ammonia. The styryl dyes include pinaflavol [101], which is used as a sensitizer in silver-based photography:

[3785-01-1]

Dyes containing nitro groups act as desensitizers (→Photography).

Styryl dyes for dyeing paper in brilliant shades are derived from quaternized γ-picoline. The dye obtained by reaction with 4-(*N*-ethyl-*N*-benzylamino)benzaldehyde has a brilliant orange color [102]:

[77770-07-1]

The shade is shifted bathochromically by ring closure at the nitrogen atom of the amino group. Using 1-ethyl-2,2,4-trimethyl-6-formyltetrahydroquinoline, a dye is obtained that colors paper a brilliant bluish red [103]. The solubility and affinity of the dyes are increased if amino and hydroxyl groups are introduced into the quaternized pyridine substituents. For example, epichlorohydrin can be reacted with morpholine and then with 4-methylpyridine [104]. Primary amines can be reacted twice with epichlorohydrin and subsequently with 2 mol of 4-methylpyridine and two equivalents of aminobenzaldehyde to form dimeric styryl dyes [105]. Dimerization may also be effected via the aldehyde component if 1 mol of 1,4-bis(formylphenyl)piperazine is condensed with 2 mol of quaternized γ-picoline [106]. If dialdehydes are reacted with dimeric γ-picolinium salts, polymeric styryl dyes are obtained that are particularly suitable for dyeing paper [107]. Polymeric dyes are also obtained by intramolecular quaternization of the reaction product of 4-methylpyridine with 4-(*N*-ethyl-*N*-chloroethylaminobenzaldehyde in ethylene glycol with the addition of pyrrolidine at 140 °C [108]. Commercial products include Astra Brilliant Orange G and Basazol C-Orange 54L.

If quaternary 4-methylpyridine is condensed with 4-acetylaminobenzaldehyde and the acetyl group is then hydrolyzed, a styryl dye with a free amino group is obtained. Methineazo dyes can be prepared from the latter by diazotization and coupling. Resorcinol [109], acetoacetamides [110], and barbituric acid [111] have been used as coupling components. The dyes are all suitable for dyeing paper.

The most important styryl dyes for textile dyeing are obtained by condensation of 4-aminobenzaldehydes with 1,3,3-trimethyl-2-methyleneindoline and its derivatives. The dye synthesized from 4-dimethylaminobenzaldehyde and 1,3,3-trimethyl-2-methyleneindoline dyes polyacrylonitrile a brilliant red shade:

[54268-66-5]

Commercial products include Basacryl Brilliant Red G, Diacryl Supra Brilliant Pink R, and Tetradene Brilliant Pink FBB.

The corresponding dye (C.I. Basic Violet 16) obtained from 4-diethylaminobenzaldehyde dyes polyacrylonitrile a more intense bluish-red shade. In 1989, 700 t of the dye were produced worldwide.

Commercial products are Astrazon Red Violet 3R, Basacryl Brilliant Red BG, Diacryl Brilliant Red 5B-F, Panacryl Brilliant Red 2B, Tetradene Brilliant Red 2B, Viocryl Violet 3RSB, and Atacryl Red Violet 3RA.

In the Vilsmeier formylation of *N*-(β-hydroxyethyl)anilines the hydroxyl group is simultaneously replaced by chlorine [112]. The resulting aldehydes condense with 1,3,3-trimethyl-2-methyleneindoline to form very brilliant dyes [113]. With 4-(*N*-methyl-*N*-β-chloroethylamino)benzaldehyde a dye is obtained that is marketed as Astrazon Pink FG, Asahiacryl Pink FGL, Aizencathilon Pink FGH and Maxilon

Pink GA. In 1989, 100 t of this dye were produced worldwide. A methyl group in the 2-position to the methine chain produces a bluish-red color:

[6441-82-3]

Commercial products include Astrazon Red 6B, Sumiacryl Red 6B, and Aizencathilon Red 6BH.

Replacement of the chlorine substituent by a cyano substituent produces a marked hypsochromic shift [114]:

[12217-48-0]

This dye (C.I. Basic Red 14) is widely used to produce brilliant red dyeings on polyacrylonitrile; 500 t were produced worldwide in 1989. For this dye as well as the aforementioned styryl dyes from 1,3,3-trimethyl-2-methyleneindoline, a new and particularly environmentally friendly process has been developed in which no effluent occurs [115–117]. Since conversion exceeds 99 %, an immediately marketable dye is obtained.

Commercial Products. Astrazon Brilliant Red 4G, Basacryl Brilliant Red X-4G, Sevron Brilliant Red 4G, Sandocryl Brilliant Red B-4G, Sumiacryl Brilliant Red 4G, Aizencathilon Brilliant Red 4GH, Concordacryl Red 4G (Concorde Dyes, Taiwan), and Rifacationic Red 4G (Rifa, South Korea).

The cyanoethyl group can be hydrolyzed to the carbamoyl group by a strong acid. The resulting dyes are exhausted from the dyebath more slowly than compounds with an unsubstituted alkyl group [118]. The adsorption rate of the styryl dyes can also be reduced by introducing alkoxyalkyl groups at the aminoaryl nitrogen atom. Examples of such dyes include Aizencathilon Brilliant Pink BH and Aizencathilon Red 7 BNH. In 1984, 100 t of Aizencathilon Red 7 BNH were produced in Japan.

Lightfastness can be improved by introducing benzyl groups [119]:

[106303-28-0]

Representatives of this series are Diacryl Supra Brilliant Red 2G and 3B as well as Aizencathilon Brilliant Scarlet RH.

The N-phenyl derivatives are even more lightfast [120]:

This range of dyes includes Astrazon Red Violet FRR and Astrazon Violet F3RL. They are used in electrophotography to make organic photoconductors [121]. Dyes derived from triphenylamine aldehyde are also suitable for the same application [122].

In addition to the unsubstituted 1,3,3-trimethyl-2-methyleneindoline, the 5-chloro derivative is often used as the heterocyclic condensation component [123]. Dyes of this series include Sandocryl Brilliant Red B-F and B-5B, and Sumiacryl Brilliant Pink F-B.

Styryl dyes with external amino groups (e.g., Kayacryl Brilliant Red 5G) are particularly suitable for dyeing polyacrylonitrile from a strongly acid medium [124]:

[43181-01-7]

The styryl dyes also include compounds in which the aminoaryl nitrogen atom is part of a carbazole (Astra Red 3G, see below) [125], phenoxazine [126], or tetrahydrobenzoxazine system [127].

[72828-91-2]

Styryl dyes that contain the carbazole ring system are used in the production of photoconducting layers in electrophotography [128].

In addition to 1,3,3-trimethyl-2-methyleneindoline, a range of other heterocyclic compounds has also been used to prepare cationic styryl dyes. 1-Phenyl-2-methylene-3-methyl-1,2-dihydroquinoxaline [129] and 1,4-dimethyl-2-methylene-1,2,3,4-tetrahydroquinoxaline-3-one [130] condense with 4-aminobenzaldehydes to form styryl dyes that dye polyacrylonitrile a greenish-blue shade.

If a base obtained from *N*-alkylnaphtholactam by reaction with methyl magnesium iodide is used, the absorption range of the styryl dyes can be extended into the near IR region:

[111720-62-8]

This dye has an absorption maximum of 760 nm and is used in the production of discs suitable for information recording with the gallium arsenide semiconductor laser [131].

If 1,2-diaminobenzene is condensed with butyrolactone and the product quaternized, a benzimidazole derivative with a reactive methylene group is obtained. Condensation of this compound with 4-aminobenzaldehydes (which can also be dimerized via the nitrogen atom) produces styryl dyes which, on account of ring closure, can be classified as monomethinehemicyanine dyes. These dyes (e.g., Basazol C Yellow 50L) are used to dye paper [132]:

Nitrogen-free heterocycles (e.g., pyrylium salts) may also be condensed to form styryl dyes. Some cationic styryl dyes are suitable as active medium in dye lasers (→ Laser Dyes).

N-heterocycles with an activated methyl group can also react with aminobenzaldehydes to form dye bases without being quaternized. These compounds are widely used in electrophotography. Derivatives of quinoline [133], benzothiazole [134], and indolenine [135] have been described. A representative of these compounds is:

[34442-71-2]

This dye base can also be transferred onto polyacrylonitrile fabric by sublimation transfer printing [136]. The carbinols of styryl dyes are also suitable for transfer printing on polyacrylonitrile [137].

Carbinol Derivatives. If the alkyl group on the indolenine nitrogen atom bears a substituent (e.g., OH, COOH, or $CONH_2$) that is capable of forming ring-closed carbinol derivatives, then stability is substantially increased. The dye with the hydroxyethyl group on the indolenine nitrogen is stabilized in an alkaline medium to form an oxazolidine derivative:

[59335-14-7]

When dissolved in propylene carbonate with the addition of tetrabutylammonium perchlorate as electrolyte, the compound is used in the production of electrochromic display elements [138]. A carboxymethyl group on the indolenine nitrogen atom closes the ring to form an oxazolone derivative. The compounds are used as color formers [139]. With a carbonamido group as substituent in the alkyl chain attached to the nitrogen, imidazolidinone derivatives [140] or hexahydropyrimidone derivatives [141] are obtained.

These compounds are more stable against ring opening by heat or protons and are therefore suitable as color formers for thermo- and pressure-copying processes.

Spiropyran Compounds. If 1,3,3-trimethyl-2-methyleneindoline is condensed with aminobenzaldehydes bearing a hydroxyl group in the 2-position to the aldehyde group, styryl dyes are obtained that are converted to colorless indolinospiropyran compounds on addition of alkali [142]. The compounds are suitable as color formers for producing colorless copying paper. In contact with acid inorganic materials (e.g., kaolin, bentonite, or attapulgite) they are cleaved into the open-chain colored form:

In spiropyran compounds derived from naphtholactam, the absorption of these color formers is shifted bathochromically to the limit of the IR spectrum [143]. Such color formers can also be prepared from aromatic 2-hydroxyaldehydes that do not contain an amino group. For example, indolinospironaphthopyran compounds that form red copies on acid clay are obtained by condensation of 1-carboxymethyl-2,3,3-trimethylindoleninium salts with 2-hydroxy-1-naphthaldehyde in the presence of triethylamine [144]:

If the 2-hydroxyaldehydes also contain nitro groups, photochromic compounds are formed that are suitable for short-term data recording. Irradiation with UV light produces an intense color which disappears on heat treatment or during storage [145]:

Storage stability of the colored form is essential for photochromic applications and can be improved either by introducing long-chain alkyl groups [146] or by incorporation into polymer systems [147].

A carboxyl group adjacent to the hydroxyl group stabilizes the open-chain form. Such compounds yield recording materials that exhibit inverse photochromism (colorless when irradiated, colored when not irradiated) [148].

Instead of indolenine, derivatives of benzothiazole [149], quinoxaline [150], pyrazole [151],

benzothiopyran [152], benzoxazine [153], and pyrimidine [154], may also be used to prepare spiropyran compounds.

Condensation of suitably substituted benzopyrilium salts with 4-(diethylamino)salicylaldehyde, produces styryl dyes with a heterocyclic terminal system in which oxygen carries the cationic charge. The spirobipyrans are obtained from the latter by ring closure, for example:

With protonating agents, a blue cation is formed by ring opening. The compounds are therefore suitable as color formers for pressure-sensitive recording materials [155]. A commercial product of this range is React Blue R (BASF).

Spirothiopyran compounds are obtained with derivatives of thiosalicylaldehyde as the starting compounds [156].

These compounds have outstanding photochromic properties and are used in the production of optical recording media. The indolenine ring system may also be substituted by amino [157] or alkoxy groups [158]. The absorption range of the open-ring compound is shifted to the near IR range ($\lambda_{max} = 780$ nm) by benzanellation. These compounds are suitable for information recording with the gallium arsenide semiconductor laser [159].

Coumarin Compounds. 7-Aminocoumarin compounds that bear a quaternized heterocycle in the 3-position may be regarded as ringclosed cationic styryl dyes. They are prepared by reacting 4-(dialkylamino)-2-hydroxybenzaldehydes with N-heterocyclic cyanomethyl compounds followed by alkylation [160]. They may also be prepared by condensation with the previously quaternized 2-cyanomethyl compounds [161].

[29556-33-0]

The iminocoumarin compound formed as intermediate may be isolated as the chlorozincate [162]. If the latter is incorporated by condensation in a toluenesulfamide-paraformaldehyde-melamine melt, a fluorescent pigment is obtained [163]. Analogous fluorescent dyes can be prepared from the cyanomethyl compounds of 2-quinazolinone [164] and pyridine [165]. A dye of this series is Maxilon Brilliant Flavin 10GFF.

The analogous quinoline dyes also fluoresce and dye polyacrylonitrile in brilliant yellow and orange shades [166].

Phenylogous Monoazadimethinehemicyanine Dyes. By reacting 4-nitroso compounds of tertiary aromatic amines with the quaternary salts of N-heterocycles containing a reactive methyl group in the 2- or 4-position, dyes similiar to styryl dyes are obtained, the CH group being replaced by nitrogen [167].

[21584-04-3]

These compounds are of no importance for dyeing because they are readily hydrolyzed at the CH = N group with the formation of the corresponding aldehydes, which are used as intermediates in the preparation of alkylarylhydrazone dyes [75], [79].

If the heterocyclic nitrogen bears a hydroxyethyl group, then an oxazolidine ring is formed in alkaline medium:

[59334-76-8]

Such compounds are suitable for multicolored electrochromic display elements [168].

Analogously to the 2-hydroxybenzaldehydes, condensation of the 2-hydroxynitroso compounds with 1,3,3-trimethyl-2-methyleneindoline yields monoazadimethine dyes that are converted to spiro compounds on the addition of alkali. They can be used as photochromic substances. Starting materials are nitrosophenols [169] and nitrosonaphthols [170].

[119995-07-2]

Phenylogous Diazadimethinehemicyanine Dyes. If N-heterocyclic compounds with an amino group in the 2- or 4-position are diazotized and then coupled to aromatic amines, yellow to red azo dyes are obtained. If these azo dyes are reacted with alkylating agents, alkylation occurs at the heterocyclic nitrogen atom. The absorption maximum of the compounds thereby undergoes a considerable bathochromic shift and becomes more intense indicating delocalization of the cationic charge. The resultant dyes are dimethinehemicyanines, in which the two CH groups have been replaced by N.

Dyes with 2-amino-6-methoxybenzothiazole as diazo component are of industrial importance because their alkylated products dye polyacrylonitrile in clear very lightfast blue shades. With *N*,*N*-dimethylaniline as coupling component, C.I. Basic Blue 54 is obtained:

[29767-87-1]

Worldwide production in 1989 was 300 t. The dye with *N,N*-diethylaniline as coupling component is also produced industrially. Dimethyl and diethyl sulfates are used as alkylating agents [171].

Commercial Products. Maxilon Blue RBL, Basacryl Blue GL, Atacryl Blue GNA, Nabor Blue AF, Diacryl Supra Blue RBL, Aizencathilon Blue BRLH, Estrol Blue GSL-SD, Yation Blue M, and Yoracryl Blue BL.

With butylcyanoethylaniline a blue dye is obtained that produces very steam-fast dyeings on polyacrylonitrile [172]. The dyes with *N*-methyldiphenylamine as coupling component dye polyacrylonitrile in greenish-blue shades. Commercial products include Basacryl Blue GGL, Maxilon Blue GL, and Kayacryl Blue GL.

The dye shown below (C.I. Basic Blue 41)

[26850-47-5]

is exhausted somewhat more slowly and can therefore be combined particularly well with other dyes. It is contained in most ranges for dyeing polyacrylonitrile. In 1988, 3000 t were produced worldwide.

Commercial Products. Maxilon Blue GRL, Sandocryl Blue B-RLE, Astrazon Blue FGGL, Basacryl Blue X-3GL, Synacril Blue G, Concordacryl Blue GRL, Nichilon Blue GRL, Panacryl Blue GRL, Viocryl Blue RLS, Yation Blue BS-S, Yoracryl Blue R-GL, Tetradene Fast Blue RL, Diacryl Supra Blue GRL.

The tetrachlorozincate of Basic Blue 41 can be prepared by adding zinc oxide or zinc carbonate as acid-binding agent in the methylation step and salting out the dye with sodium chloride [173]. Stable, highly concentrated solutions of the aforementioned dyes are produced by performing the methylation in mixtures of water and glycols, glycol ethers, or ethylenecyanohydrin [174].

Many diazadimethine dyes decompose during dyeing in a weakly acid to neutral medium, whereby accompanying fibers can be stained. This hydrolysis is suppressed by complexing anions such as benzoate, benzenesulfonate, or phenolate ions [175]. Dyes that are more stable to

hydrolysis are obtained if derivatives of indoline [176] or tetrahydroquinoline [177] are used as coupling components.

The exhaustion rate can be reduced by introducing ether [178] and polyether groups [179] into the aminoalkyl group of the coupling component. The same effect is achieved if the diazo component is substituted by a dioxane ring [180]. Dyes that show a lower affinity for the wool fiber in mixed fabrics are substituted on the aminoaryl nitrogen by acyloxy groups. Suitable coupling components are the benzoates or carbonates of *N*-ethyl-*N*-hydroxyethylaniline [181] or the carbamates obtained by reaction with phenyl isocyanate [182]. With diisocyanates dimeric dyes are obtained that are suitable for spin dyeing polyacrylonitrile [183]. If diazacyanine dyes bearing a free amino group in the benzothiazole group are dimerized via a urea bridge, dyes are obtained that are suitable for dyeing paper [184]. The above dyes, in particular those whose aminoaryl nitrogen is part of a ring, include compounds that are suitable as photoreceptors for electrophotographic applications [185].

The quaternization of heterocyclic azo dyes to form diazadimethine dyes can also be carried out in an acid medium if compounds containing vinyl groups are added to the protonated azo dyes. Acrylic acid [186], acrylates [187] and, in particular, acrylamide [188] are suitable for this purpose. The following dye

[85959-18-8]

colors polyacrylonitrile in greenish-blue shades. Commercial products are Aizencathilon Blue NBLH, NRLH, GLH, and Atacryl Blue LLR, LL2R.

In acid medium oxiranes, in particular ethylene oxide [189], propylene oxide (see below), butylene oxide and their substitution products [190], can also add on to heterocyclic azo dyes:

Commercial products include Yation Blue BS, BRS, GRS, Sumiacryl Blue F-GSL, Daitoacryl Blue GL, Acrylon Blue BLN, and Estrol Blue N-BRL.

With 2-aminothiazole as diazo component, violet to reddish-blue dyes are obtained [191]. If the coupling components have a low molecular mass, the dyes exhibit a high leveling ability [192]. One example of this is the migrating blue dye:

[71196-94-6]

Biscationic dyes, which are usually used for spin dyeing polyacrylonitrile, are also derived from thiazole [193]. The following compound

dyes acrylic fibers blue with good steam fastness [194]. Commercial products are Diacryl Supra Blue BL, Sumiacryl Blue G, and Atacryl Violet L6B.

With 3-methyl-5-aminoisothiazole as diazo component, lightfast and decatizing-fast diazacyanine dyes for dyeing polyacrylonitrile are obtained. The dye

[105890-17-3]

colors polyacrylonitrile a reddish-blue shade [195]. Other suitable coupling components are tetrahydrobenzoxazine [196] and tetrahydroquinoxaline [197].

The coupling of diazotized 3-amino-1,2,4-triazole to aromatic amines affords azo dyes that require two equivalents of an alkylating agent to convert them to diazadimethine dyes. A mixture of two isomeric dyes is obtained, e.g.,:

Main component [*74109-48-1*]

Byproduct [*47089-11-2*]

Dyes that are obtained with *N,N*-dimethyl- and *N,N*-diethylaniline as coupling component and with dimethyl or diethyl sulfate as alkylating agent dye polyacrylonitrile in lightfast bluish-red shades [171], [198]. They have a lower affinity for polyacrylonitrile, but on account of their low molecular mass they are exhausted with a high diffusion rate by the fibers. They are therefore particularly suitable for producing level dyeings in light shades. The same dyes can also be formed with 3-amino-1,2,4-triazole-5-carboxylic acid as diazo component since the azo dyes can easily be decarboxylated [199].

Commercial Products. Maxilon Red BL, Sandocryl Red B-BLE, Astrazon Red F3BL, Synacril Red 3B, Basacryl Red MX-BL, Bezacryl Red BL, and Tetradene Fast Red CBL. In 1989 300 t of Basic Red 22 were produced worldwide.

The affinity of the dyes for polyacrylonitrile and accordingly their exhaustion rate is increased by introducing aromatic groups. Basic Red 46 is of particular industrial importance:

[*29508-47-2*]

In 1988, 1500 t of this dye were produced worldwide.

Commercial Products. Maxilon Red GRL, Astrazon Red FBL, Basacryl Red X-GRL, Aizencathilon Red FG-DP, Estrol Red GSL-SD, Panacryl Red GRL, Sandocryl Red B-RL, Sevron Fast Red GRL, Synacril Red G, and Yoracryl Red BGL.

N,N-Dibenzylaniline and *N*-methyldiphenylamine as well as the arylcarboxylates and aryl carbonates of *N*-(hydroxyethyl)aniline are also used to increase the exhaustion rate. Arylalkyl radicals in the 1-position of the triazole ring likewise increase the exhaustion rate [200]. The commercial products are Aizencathilon Red FRLH, Basacryl Red FL, and Maxilon Red 3BL.

Diazotization, coupling, and quaternization can also be combined in a one-pot process for this class of dyes [201]. Pure dyes are isolated if the separation is performed in the presence of nonionic surfactants [202]. To produce highly concentrated dye solutions, only part of the azo base is added at the start of the reaction, the remainder being added to the dye melt during the methylation process [203]. Many dyes of the triazolediazacyanine series tend to agglomerate during storage. Exceptions are the hydrobromic acid salts [204].

The introduction of a methyl group in the 2-position relative to the azo bond increases stability of these dyes in the dye bath [205]. Dyes that are dimerized by an alkylene bridge via the aminoaryl group are suitable for dyeing porous polyacrylonitrile fibers (Dunova) [206] and for spin dyeing polyacrylonitrile from the gel state [207]. (Commercial product is Diacryl Red 2BLE.)

Additive alkylation in an acid medium with alkylene oxides [208], acrylonitrile [209], acrylamide [210], and acrylic acid [211] has also been described for the triazole dye series.

Two series of dyes are derived from 3,5-diamino-1,2,4-triazole [*1455-77-2*], also known as guanazole. The monoazo dyes form red diazadimethine dyes after alkylation [212]:

A commercial product of this series is Aizencathilon Red K-BLH. The bisazo dyes formed from guanazole produce reddish-blue diazadimethine dyes on alkylation [213], e.g.,:

Commercial products include Aizencathilon Marine Blue RLH, GRLH, and Aizencathilon Royal Blue GH.

Blue diazadimethine dyes with a high dye bath stability are derived from 2-amino-5-dialkylamino-1,3,4-thiadiazole. The following dye

[83930-05-6]

also has a very good leveling ability [214]. The commercial products are Astrazon Blue FBL [*81921-76-8*] and FGRL.

Orange to red diazadimethine dyes are obtained in a similar manner with 3-aminopyrazole as diazo component [215]. The nitrogen atom in the 2-position of pyrazole can be substituted by a cyclohexyl, benzyl [216], or phenyl group [217]:

[68123-01-3]

Commercial products are Maxilon Orange 4RL and Basacryl Red X-GFL, X-3GL.

The nitrogen atom in the 1-position may also bear a phenyl group [218]. Partially hydrogenated N-heterocycles such as tetrahydroquinoline [219] and tetrahydrobenzoxazine [220] may also be used as coupling components.

Benzoanellation of pyrazole produces a considerable bathochromic shift; the corresponding indazole dyes are therefore violet to blue [221].

[73507-56-9]

Alternatively, indazole dyes can also be prepared by oxidative coupling of 1,2-dialkylindazol-3-one hydrazone with aromatic amines [222]:

[28219-31-0] [102-56-7]

A further synthesis route is the condensation of a 1,2-dialkylindazolium-3-sulfonate with a 4-acylaminophenylhydrazine, followed by oxidation [223].

Commercial products are Basacryl Violet FL, Maxilon Violet RL.

In contrast to the aforementioned N-heterocyclic compounds, imidazole may be used as coupling component for diazotized aromatic amines. Dyes with primary amino groups are obtained by coupling diazotized 2- or 3-chloro-4-aminoacetanilide with imidazole, methylating the resultant azo dye to form the diazacyanine, and finally hydrolyzing the acetyl group in acid medium [224]. The dye of the formula

has an outstanding migration ability and accordingly dyes polyacrylonitrile in a lightfast orange shade with high levelness. Reaction of diazo components containing chlorine or a methoxy group in the 4-position to the amino group with imidazole, and subsequent quaternization yields compounds in which the halogen or alkoxy substituents (in the 4-position to the azo group) can be replaced by amino groups [225]. The dyes obtained with lower aliphatic amines (e.g., C.I. Basic Red 51)

[12270-25-6]

color polyacrylonitrile in lightfast red shades

[226]. On account of their low molecular mass they have a high diffusion rate and are therefore particularly suitable for producing level combination dyeings.

Commercial products of Basic Red 51 include Basacryl Red X-BL, Basacryl Red Violet X-GL, and Maxilon Red M-4GL, M-RL.

Biscationic dyes of the imidazole series are particularly suitable for dyeing acid-modified polyamide fibers [227]. 2-Aminopyridine cannot be converted directly to its diazonium salt. The following violet diazadimethine dye is therefore prepared indirectly via the 2-aminopyridine-*N*-oxide [228]:

[3068-74-4]

Alternatively, 2-aminopyridine can be reacted with 4-nitroso-*N,N*-dialkylanilines in the presence of sodium amide, followed by quaternization [229]. These dyes are used in analytical chemistry for spectrophotometric determinations [230], [231]. They are also used as hair dyes [232].

A series of N-heterocycles with amino groups (e.g., 4-amino-2-methylquinoline) can also be diazotized as quaternary salts and coupled to form diazadimethine dyes [233]. The following dye gives polyacrylonitrile a blue color:

Red to blue-violet dyes for polyacrylonitrile are obtained by oxidative coupling of 2-alkylpyridazonehydrazone-3-derivatives with aromatic amino compounds [234], e.g.,:

2-Aminothiophene derivatives can be condensed by reaction with potassium thiocyanate and oxidative ring closure to form 2-aminothiophenothiazoles. These heterocyclic amino compounds are starting material for the production of blue diazacyanine dyes [235]. The dye of the formula

[68560-36-1]

colors polyacrylonitrile a clear greenish-blue shade.

7.3.3. Higher Vinylogs of Phenylogous Hemicyanine Dyes

Condensation of 4-(dialkylamino)cinnamaldehydes with N-heterocycles that bear a reactive methyl or methylene group in the 2- or 4-position to the heterocyclic nitrogen atom produces tetramethinehemicyanine dyes, which are vinylogs of styryl dyes. The dye synthesized from quaternary 2-methylbenzothiazole absorbs at 572 nm. The cyano-substituted dye of the formula

[61502-93-0]

obtained from 2-cyanomethylbenzothiazole exhibits a strong bathochromic shift with an absorption maximum of 647 nm [236].

7.3.4. Phenylogous Hemicyanine Dyes with Rings in the Methine Chain

In the higher vinylogs of phenylogous hemicyanine dyes the methine chain may also be part of a ring; this increases the stability of the dyes. The dye

absorbs at 600 nm and is used for optical data storage. This dye is prepared by reacting quaternary 2-methylbenzothiazole with 4-methylbenzopyran-2-thione and condensing the resultant quaternary intermediate with 4-dimethylaminobenzaldehyde [237].

7.4. Cyanine Dyes

In cyanine dyes both charge-carrying terminal atoms of the methine chain are constituents of heterocyclic rings. Depending on the nature of the heterocycle, the methine chain may be coupled in the 2-, 3-, or 4-position to the charge-carrying terminal atom. Accordingly, either one, two, or three ring atoms participate directly in the mesomeric methine system.

According to the general definition of methine dyes, the number of atoms in the conjugated system must always be an odd number. In symmetrical dyes the sum of the charge-carrying atoms in both heterocyclic rings is always even. The methine chain must therefore contain an odd number of atoms. In cyanine dyes with different heterocyclic groups, however, the sum of the atoms involved in the charge-conducting system in both rings can be an odd number. In this case the methine chain must contain an even number of atoms. Cyanine dyes with a substituted methine chain or in which parts of the chain are constituents of a ring are particularly important in photography (→Photography).

7.4.1. Zeromethinecyanine Dyes

Naphtholactam and its N-alkyl derivatives can be condensed with indoles in the presence of acid condensation agents such as phosphorus oxychloride to form red zeromethinecyanine dyes that dye polyacrylonitrile very lightfast shades [238]. The indole may contain a methyl or phenyl group in the 2-position. If the 2-position is not substituted, the coloring strength increases because there is less steric hindrance [239], e.g.,:

Condensation of indoles with N-alkylquinolones or N-alkylpyridones yields yellow and orange zeromethine dyes that dye polyacrylonitrile in lightfast shades [240]. If the indole nitrogen is unsubstituted, intensely colored anhydro bases are formed from the zeromethinecyanine dyes. Dealkylation of the heterocyclic quaternary nitrogen atom also occurs [241].

The second heterocyclic ring of the zeromethinecyanine dyes can also be formed in the last synthesis step. The methylene group of 1,3,3-trimethyl-2-methyleneindoline can react with alkylene oxides at elevated temperature. If the hydroxyl group is replaced by a halogen and the resultant compound is coupled with aromatic diazonium salts, intramolecular alkylation occurs simultaneously and a pyrazoline ring is formed. These dyes color polyacrylonitrile in brilliant, fluorescent shades that are extremely lightfast [242]:

The solubility of these dyes is increased by introduction of polyether groups [243].

7.4.2. Monomethinecyanine Dyes

The oldest dye of this series is *cyanine*, a blue dye after which the whole class of dyes was named. Cyanine was synthesized by WILLIAMS

in 1856 from crude tar quinoline by quaternization with pentyl iodide, followed by treatment with alkali:

[862-57-7]

The unsymmetrical monomethine dye coupled in the 2- and 4-position of quinoline is termed *isocyanine*. Monomethine dyes containing two molecules of quinoline coupled to each other in the 2-position (also called pseudocyanines) are obtained by the alkaline-catalyzed reaction of *N*-alkylquinaldinium salts with quinolinium compounds [244]:

[977-96-8]

Monomethinecyanine dyes of indolenine are obtained by reaction of 1,3,3-trialkyl-2-methylindoleninium salts with esters or salts of nitrous acid in the presence of acetic anhydride. A nitroso compound is formed which reacts with a further mole of the indoleninium salt with the elimination of hydrocyanic acid to form a monomethine dye [245]:

[6359-44-0]

This class of dyes colors tanned cotton, cellulose acetate, and polyacrylonitrile in greenish yellow shades with good lightfastness. The unsubstituted dye of this series was converted with phosphomolybdotungstic acid into a yellow pigment.

The allene compound is obtained by the action of sodium hydride on the monomethine dye [246].

The benzoxazolemonomethinecyanine dyes are obtained in a similar way to the monomethinecyanine indolenine dyes [247].

[47296-06-0]

These dyes are suitable for sensitizing silver chloride emulsions for the violet and blue regions of the spectrum. Bacteriostatically active dyes have also been discovered in this series [248]. Their intense blue-violet fluorescence makes them suitable for use as lightfast and washfast brighteners for natural and synthetic fibers [249]. Uvitex ALN is a commercial product of this range.

The hydrogen at the methine carbon atom in monomethine dyes can be reversibly substituted by halogen [250]. Monomethinecyanines can be coupled with aryldiazonium salts at the central (meso)-carbon atom to form mesoarylazomonomethinecyanines, which according to their absorption spectra have a phenylhydrazone structure [251].

If the methyl or methylene group of the N-heterocycle is activated by a substituent (e.g., a cyano group), it can be condensed directly with the relevant carbonyl compound in the presence of a dehydrating agent, especially phosphorus oxychloride. *N*-alkylnaphtholactam [252] and its derivatives [253] condense with 1,3,3-trimethyl-2-cyanomethyleneindoline to form red and violet dyes that dye polyacrylonitrile in lightfast shades:

2,6-Diphenyl-[2*H*]-pyran-4-one condenses with acetophenone to form the following pyryliummonomethine dye:

[47793-49-7]

This dye absorbs in the IR region [254] and is used to prepare nonerasable optical recording materials [255].

The monoazamonomethinecyanine dyes are obtained by reaction of imines of benzothiazol-2-ones with strong, preferably anhydrous acids [256]:

[66179-76-8]

The compounds display blue fluorescence and are used as optical brighteners (e.g., Ultraphor AL, BASF) for polyacrylonitrile [257].

7.4.3. Dimethinecyanine Dyes

In the most important dimethinecyanine dyes the methine chain links two indole moieties in the 2- and 3-positions.

The dyes were initially used for dyeing and printing cellulose acetate [258], but became increasingly important when it was discovered that they can dye polyacrylonitrile in brilliant and lightfast shades.

C.I. Basic Orange 21

[47346-66-7]

is prepared either from 2-methylindoline-3-aldehyde and 1,3,3-trimethyl-2-methyleneindoline or from 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde and 2-methylindole. It is used in many ranges for dyeing polyacrylonitrile. In 1989, 250 t were produced worldwide.

Preparation. 1230 kg of 30 % hydrochloric acid are brought into a 1500-L enameled vessel, followed by 104 kg of 2-methylindole at room temperature, while stirring. When the 2-methylindole has completely dissolved after 1 – 2 h, 154 kg of 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde is quickly added at room temperature and the reaction mixture is stirred for 24 h at room temperature; the dye starts to crystallize after ca. 15 min. The reaction mixture is diluted with 400 L of cold water and the dye suspension is suction filtered, washed twice with 200 L of cold water, and thoroughly dried under suction. After drying at 95 – 100 °C, a yield of 323 kg is obtained, corresponding to 1043 kg of commercial product.

Commercial Products. Astrazon Orange G, Maxilon Orange GA, Aizencathilon Orange GLH, Asahiacryl Orange GL, Atacryl Orange LR, Cathilon Orange GL, Concordacryl Orange GL, Hispacril Orange G, Kayacryl Orange 2G, Nabor Orange G, Sumiacryl Orange G, Viocryl Orange GLS, and Yation Yellow RM.

A red-orange dye is prepared in a similar manner from 1-methyl-2-phenylindole. The commercial products are Astrazon Orange R, Maxilon Orange RA, Aizencathilon Orange RLH, Nabor Orange R, and Sumiacryl Orange R.

If this dye is reacted with an aqueous solution of potassium cyanide, the cyanide group is introduced into the 2-position of the indoline ring system and the dye is decolorized [259].

Dimethinecyanine dyes in which the indole ring is unsubstituted in the 2-position are used for dyeing polyacrylonitrile and for histological staining [260].

Reaction of pyrrole-2- [261] and pyrazole-4-aldehydes [262] with 1,3,3-trimethyl-2-methyleneindoline has also been described. The resultant dimethinecyanine dyes color polyacrylonitrile yellow. Dimethinecyanine antipyrine dyes are obtained by condensation of 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde with a pyrazol-5-one and subsequent alkylation. The following dye

dyes polyacrylonitrile in reddish-yellow shades. Dimethinecyanine dyes prepared by condensation of indole-3-aldehydes with N-alkyl-γ-picolinium salts [264] color paper brilliant yellow shades:

[64651-39-4]

Diazadimethinecyanine dyes are formed by coupling diazotized N-heterocyclic amines in the β-position to the nitrogen atom of other heterocycles followed by alkylation. The most important coupling agent is 1-methyl-2-phenylindole. Reaction of this compound with diazotized 2-aminothiazole and subsequent methylation with dimethyl sulfate, yields a dye that draws up very quickly on polyacrylonitrile and dyes it a lightfast red shade [265]:

[42373-04-6]

Commercial products re Basacryl Red GL, Cat acryl Red GL, and Diacryl Red GL-N.

Additive alkylation with acrylamides yields dyes that have a medium sorption rate [266]:

[50905-70-9]

Commercial products nclude Aizencathilon Red GLH and Atacryl Scarlet LL7B.

N-Alkylation with alkylene oxides and their derivatives also yields dyes of medium sorption rate [267]. Commercial products are as follows: Diacryl Red CS-N, Estrol Red N-GL, Sumiacryl Red FRL, N-RL, and Yation Red GS.

Coupling diazotized 3-amino-1,2,4-triazole with 1-methyl-2-phenylindole and double alkylation, yield dyes that dye polyacrylonitrile in lightfast, reddish-yellow shades [268]:

Commercial products nclude Basacryl Yellow 5RL, Aizencathilon Yellow DS-DP, Diacryl Yellow 2RN, Estrol Yellow N-2RL, Genacryl Yellow RRL, Kayacryl Yellow 3RL-ED, and Sumiacryl Yellow F-2RL.

Dyes that have dodecyl sulfate as an anion are suitable for spin dyeing polyacrylonitrile from acetone solution [269]. In this series of dyes additive alkylation can also be successfully performed with alkylene oxides [270] or cycloalkylene oxides [271].

Diazacyanine dyes with two different alkyl substituents on the triazole nitrogen atoms are obtained by coupling diazotized 3-amino-1-benzyl-1,2,4-triazole to 1-ethyl-2-phenylindole and quaternizing the azo dye with dimethyl sulfate or, in the acid pH range, with acrylamide to form the diazacyanine dye [272]. The commercial products are Aizencathilon Yellow 3R-DP, K-3RLH, and RPLH.

Mono- and bisdiazacyanine dyes are derived from guanazole. Whereas the monodiazacyanine dyes dye polyacrylonitrile reddish-yellow shades [273], the bisdiazacyanines [274] produce red dyeings, e.g.:

Dyes with 3-aminopyrazole or its derivatives [275] as diazo component dye polyacrylonitrile yellow, e.g.:

[33639-59-7]

The tetrafluoroborate of this dye is used for spin dyeing polyacrylonitrile [276]. Commercial products are Maxilon Yellow GL and Basacryl Yellow X-GL.

Benzoanellation of pyrazole produces a bathochromic shift (e.g., Basacryl Orange FL) [277]. Further suitable heterocyclic starting components are the amino derivatives of *N*-methyl-benzimidazole [278], 4,5-dicyanoimidazole [279], and pyridine [280].

7.4.4. Trimethinecyanine Dyes

Trimethinecyanine dyes are important sensitizers in photography (→Photography). The first sensitizer for the longwave red region was cryptocyanine [*4727-50-8*], obtained from quaternized lepidine:

Sensitization maximum: 735 nm

Even more important was pinacyanol [*605-91-4*], which was obtained from quaternary quinaldine by reaction with formaldehyde to form the leuco compound and atmospheric oxidation in an alkaline medium [281]:

Sensitization maximum: 637 nm

Oxidation can also be performed in an acid medium. Suitable oxidizing agents are atmospheric oxygen, lead dioxide, or chloranil [282]. Oxidation is not necessary if condensation is carried out with chloroform, bromoform, or iodoform [283]. The Vilsmeier complex formed from phosphorus oxychloride and dimethylformamide is also suitable for introducing the middle methine carbon atom [284]. Pinacyanol is used as an electrophotographic photoreceptor [285]. This class of dyes also includes compounds having antimicrobial properties [286]. Fluorine-containing substituents (e.g., the trifluoromethylsulfonyl group) produce a bathochromic shift of the absorption maximum [287]. The trifluoromethylsulfonyl substituent has also been introduced into trimethinecyanine dyes of the benzimidazole series by condensation of the substituted quaternary salt with triethyl orthoformate [288].

Astraphloxin [*6320-14-5*] is obtained by reaction of 2 mol of 1,3,3-trimethyl-2-methyleneindoline with 1 mol of orthoformate [289] or other formic acid derivatives [290]:

This compound dyes polyacrylonitrile, cellulose acetate, and paper in brilliant red shades. It is used in the form of its phosphomolybdotungstic salt [291] or as the tetraphenyl borate [292] to produce colored toners for electrophotographic applications. An improved process for preparing astraphloxin uses the mixed anhydride of acetic and formic acids (formed by reacting acetic anhydride with sodium formate) to introduce the methine carbon atom in the meso position [293].

Preparation. A mixture of 200 kg of glacial acetic acid and 200 kg of acetic anhydride is cooled to −6 °C. Sodium formate (93.2 kg) is added and produces a weakly exothermic reaction: the temperature rises to 2 – 6 °C. The resulting suspension thickens on prolonged stirring. When the temperature reaches 5 °C 200 kg of 1,3,3-trimethyl-2-methyleneindoline is added, the temperature increases to 10 – 15 °C. As soon as all the base has been added, the brine cooling is removed and the reaction mixture is stirred for 1 h, the temperature rises to 20 °C. The reaction mixture is heated for one more hour at 50 – 53 °C and stirred for a further 18 h at this temperature. If the 1,3,3-trimethyl-2-methyleneindoline con-

tent is still greater than 1 %, the melt is stirred for a further 5 – 10 h at 50 – 53 °C. The reaction mixture is then diluted with 150 L of water and stirred for 30 min at 50 °C until it is homogeneous. The condensation reaction mixture is then added to a 35 – 40 °C solution of 210 kg of 30 % hydrochloric acid in 2800 L of water. After cooling the mixture to room temperature, the dye is salted out with 500 kg of sodium chloride. The suspension is stirred for 5 h at room temperature, filtered, and washed with a solution of 15 kg of 30 % of hydrochloric acid and 90 kg of sodium chloride in 850 L of water. Finally, the press cake is washed with a solution of 95 kg of sodium chloride in 850 L of water. A yield of 229 kg of astraphloxin is obtained.

To prepare a concentrated liquid dye formulation, when the 1,3,3-trimethyl-2-methyleneindoline content has fallen to < 1 %, the following components are added to the condensation melt at 50 °C: 43 kg of glacial acetic acid, 75 kg of ethylene glycol, 11 kg of the addition product of 40 moles of ethylene oxide with oleyl alcohol, and 140 kg of water. This solution can be used directly to dye paper containing wood pulp.

The lightfastness of trimethinecyanine dyes is considerably improved by introducing cyano groups into the methine chain [294]. *N*-alkylnaphtholactam can be converted into the corresponding methylene compound by the Grignard reaction [295]. Condensation of the latter with 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde and its substitution products yields violet to blue dyes for dyeing polyacrylonitrile. The cyano-substituted dyes are very lightfast [296].

Blue and green trimethinecyanine dyes are obtained with 3-methyl-2-methylene-1-phenyl-1,2-dihydroquinoxaline as condensation component [297]. Introduction of pyrylium terminal groups extends the absorption range further into the IR region. The following dye is obtained by condensation of 4-methyl-2,6-diphenylpyrylium perchlorate with dimethoxyethylacetate [298].

[48236-64-2]

In order to prepare unsymmetrical pyrylium dyes, 4-formyl-2,6-diphenyl-methylenepyran is reacted with pyrylium salts. Thiopyrylium dyes can also be obtained in the same way [299]. The dyes are used for nonerasable optical data storage [300]. Trimethinecyanine dyes with benzopyrylium [301], benzothiazolium, and benzimidazolium terminal groups [302] are also suitable for this purpose. Trimethinecyanine dyes with benzopyrylium terminal groups are used in electrophotography to produce organic photoconductors [303].

Monoaza-, Phospha-, and Arsatrimethinecyanine Dyes. If the methine groups in the α-position are replaced by *nitrogen*, a marked hypsochromic shift is produced. With the following dye

[31787-22-1]

this shift is 81 nm [304]. These dyes are used to produce organic photoconductors [305]. If, however, the β-methine group is replaced by nitrogen, a bathochromic shift of about 55 nm is produced.

To synthesize *β-phosphatrimethinecyanine* dyes, 1,3,3-trimethyl-2-methyleneindoline is reacted with phosphorus tribromide to form bromo-bis(1,3,3-trimethylindoline-2-ylidenemethyl) phosphane, which is then reacted with trimethyloxonium tetrafluoroborate. The replacement of the β-methine carbon atom by phosphorus leads to a bathochromic shift of 33 nm (λ_{max} = 586 nm) [306].

Similiarly *arsatrimethinecyanine* dyes are obtained with arsenic tribromide. The maximum

bathochromic shift in this case is considerable: 111 nm (λ_{max} = 664 nm) [307].

Diazatrimethinecyanine Dyes. The reaction of *N*-alkylbenzothiazol-2-onehydrazones with benzimidazole-2-aldehydes produces dye bases which can be alkylated to give greenish-yellow diazatrimethinecyanine dyes. These dyes fluoresce strongly and dye polyacrylonitrile brilliant shades [308]. They are also used as fungicides for aquatic animals [309].

Commercial products are Basacryl Yellow 5GL and Kayacryl Brilliant Yellow 5GL.

Diazatrimethinecyanine dyes can also be prepared by coupling diazotized 2-aminobenzothiazole or 3-amino-1,2,4-triazole with benzimidazol-2-yl acetic acid, decarboxylation, and alkylation of the heterocyclic nitrogen atoms [310]. Oxidative coupling of heterocyclic hydrazones with *N*–heterocycles containing reactive methyl or methylene groups can also be employed [311].

Cyano-substituted diazatrimethinecyanine dyes are obtained from cyanomethyl or cyanomethylene derivatives. For example, diazotized 2-aminobenzothiazole can be coupled with 2-cyanomethylbenzimidazole or 1,3,3-trimethyl-2-cyanomethyleneindoline, the resultant dye bases are alkylated [312].

Triazatrimethinecyanine Dyes. Replacement of all three methine groups of trimethine dyes by nitrogen results in a hypsochromic shift. Such compounds are synthesized by diazotizing a heterocyclic amine and coupling with the same or another amine. The resultant triazene is alkylated to give the triazatrimethine dye [313]. The following compound

[3068-61-9]

dyes polyacrylonitrile a brilliant, very lightfast yellow-orange shade. Corresponding dyes containing benzimidazole terminal groups are obtained by reacting 2-chloro-1,3-diethylbenzimidazolium tetrafluoroborate with sodium azide to form the azidinium salts, followed by reaction with sodium azide in dimethylformamide [314].

7.4.5. Pentamethinecyanine Dyes.

Pentamethinecyanine dyes can be obtained analogously to trimethinecyanine dyes from the methyl-substituted heterocyclic quaternary salts by condensation with β-ethoxyacrolein acetal [315] or malonaldehyde tetraethyl acetal [316] in the presence of acetic anhydride or pyridine. The vinylogous dye of pinacyanol synthesized from quaternary quinaldine absorbs in the IR region (λ_{max} = 813 nm) and is used to produce nonerasable storage discs for optical information recording [317]:

[14187-31-6]

Dyes with a substituted central methine carbon atom are obtained from the correspondingly substituted malonaldehydes. The introduction of electronegative substituents into the meso-position of the pentamethine chain produces, in contrast to the trimethinecyanine dyes, a hypsochromic shift of the absorption maximum. The dye prepared from sodium nitromalonaldehyde and quaternary quinaldine absorbs at 660 nm (i.e., at a 153 nm shorter wavelength than the unsubstituted dye). Bromine, chlorine, fluorine and cyano or carboethoxy groups can be introduced into the meso-position [318]. The influence of substituents has been investigated with ^{13}C-NMR-spectroscopy [319].

Pentamethinecyanine dyes that are substituted in the meso-position by an azo group are obtained with arylazomalonaldehydes [320]. Aminomalonaldehydebisdimethylacetal, which serves as a starting material for meso-acylamino-substituted pentamethinecyanine dyes, is obtained by catalytic hydrogenation of the arylazomalonaldehyde [321]. Dialkylaminomalonaldehydes, which are start-

ing compounds for the synthesis of dialkylaminopentamethinecyanines, can be prepared from bisdialkylaminoethylenes by the Vilsmeier reaction [322]. Pentamethinecyanine dyes with benzo[*c,d*]indolenine [323] and pyrylium [324] terminal groups absorb in the IR region and are used to produce nonerasable optical storage media.

Tetraazapentamethinecyanine Dyes. Aliphatic or aromatic aldehydes react with N-heterocyclic hydrazones to produce aldazines, which react with a further mole of the heterocyclic hydrazone in the presence of oxidizing agents to form tetraazapentamethinecyanine dyes. The dye

[*94108-98-2*]

colors polyacrylonitrile a lightfast green shade.

7.4.6. Higher Vinylogs of Cyanine Dyes

Heptamethinecyanine dyes are obtained by reacting the quaternary salts of 2- or 4-methyl-N-heterocycles or the corresponding methylene compounds with pentamethinestreptocyanine dyes (see Section 7.1.2). For example, condensation of glutaconaldehydedianil with 1,3,3-trimethyl-2-methyleneindoline yields

[*126609-59-4*]

which is used to produce nonerasable optical storage media [326].

Use of the complex salts of these dyes with phosphorus-containing heteropolyacids (e.g., phosphomolybdate, phosphotungstate, or phosphotungstomolybdate) has also been suggested for the same purpose [327]. Heptamethinecyanine dyes containing sulfonic acid groups and indolenine terminal groups are used as IR filter dyes [328].

Substitution of the dyes in the central (meso)-position produces a hypsochromic shift of the absorption bands in the case of electron donors and a bathochromic shift in the case of electron acceptors [329]. Nonamethine dyes and higher vinylogs are obtained from the corresponding streptocyanine dyes and heterocyclic quaternary salts [330].

7.4.7. Cyanine Dyes with Rings in the Methine Chain

The stability of polymethine dyes is improved by incorporation of ring systems in the methine chain [331]. Suitable starting materials are the dialdehydes obtained by the Vilsmeier reaction from cyclohexanone and cyclopentanone [332]. Reaction of the dialdehyde derived from cyclopentanone with 2-methyl-4,6-diphenylpyrylium perchlorate yields [333]:

[*61010-22-8*]

λ_{max} = 1.095 nm, ε = 167000

The above aldehydes react with 1,3,3-trimethyl-2-methyleneindoline and its substitution products to yield IR-absorbing dyes. These dyes are brought together with sublimable dyes onto a transfer ribbon. The absorption of laser energy and the dye transfer in laser video printing is thus improved [334]. The halogen atom in the meso-position can be substituted by amines [335] to give dyes that serve as sensitizers in electrophotography. Replacement of the halogen by compounds with a reactive methylene group (e.g., malononitrile [336] or barbituric acid [337]) leads to the formation of IR-absorbing dyes that are used to produce nonerasable optical storage elements. The absorption range of this class of dyes can be increased to 1328 nm by vinylogous chain extension [338].

7.4.8. Cyanine Dyes with Several Methine Chains

Branched cyanine dyes are obtained by reacting triformylmethane with N-heterocyclic quaternary salts or the corresponding methylene compounds. With 1,3,3-trimethyl-2-methyleneindoline the following dye is obtained [339]:

[80137-15-1]

A propeller-like configuration has been confirmed by ^{13}C-NMR spectroscopy, demonstrating its structural similarity to the triphenylmethane dyes [340].

Monomethinecyanine dyes with the 2,6-dimethylpyrylium terminal system can be reacted with aromatic or heterocyclic aldehydes to give dyes containing several methine chains [341]. The following dye

[105845-39-4]

is used as an organic photoconductor in electrophotography.

8. Anionic Methine Dyes (Oxonols)

Anionic methine dyes are formed by elimination of a proton from their conjugated acids:

Since oxygen is the charge-carrying terminal atom in the majority of these dyes, they are also termed oxonols. The simplest member of this series is the sodium salt of malonaldehyde; the next higher vinylog is the sodium salt of glutaconaldehyde:

Only oxonol dyes derived from cyclic compounds containing reactive methylene groups are important in dyeing. They are used in the protonated form in acid media as disperse dyes.

8.1. Monomethineoxonol Dyes

The following symmetrical monomethineoxonol dye was first synthesized by E. Besthorn and L. Knorr in 1897 by the reaction of 1-phenyl-3-methylpyrazol-5-one with chloroform and alkali:

[*4174-09-8*]

Other reactants for synthesizing these dyes include orthoformates, dialkyl or alkylarylformamides and, in particular, formamide [342].

Unsymmetrical monomethineoxonol dyes are obtained by Vilsmeier formylation of pyrazolone derivatives and reaction with a further molecule of pyrazolone [343]. The compounds exist in the cis-form as 8-membered ring proton chelates [344]. The dyes are suitable for dyeing and printing textiles made from aromatic polyesters, polyamides, polyurethanes, and cellulose esters [345]. The dyes are also employed for extremely lightfast transparent varnishes [346]. The 4,4'-methinebis(pyrazolone) dyes are used for the transparent dyeing of thermoplasts such as polystyrene and poly(methyl methacrylate). The commercial products are Macrolex Yellow G (Bayer) and Thermoplast Yellow G (BASF).

Metal salts of 5,5'-methinebis(barbituric acid) derivatives are used as pigments for dyeing poly(vinyl chloride) [347].

The fulgides discovered by H. G. Heller may be classified as monomethineoxonol dyes. A typical representative is obtained as follows:

Irradiation at 366 nm converts the pale yellow monomethineoxonol dye (**3**) into the deep red cyclic oxonol (**4**). When irradiated with visible light (**4**) undergoes ring opening into the pale yellow monomethine oxonol (**3**). In contrast to other photochromic compounds, both forms are stable. Investigations aimed at using these compounds for the production of erasable optical memories are underway [348]. Long-chain groups on the methine carbon atom further stabilize the two forms [349]. Imides may also be used instead of anhydrides [350].

Dispersol Red CB-N (ICI) is also a cyclic oxonol dye. It contains a double oxonol structure as indicated by the dotted line [351]:

[*79694-17-0*]
λ_{max} = 506 nm

The ammonium salt of purpuric acid (murexide [*3051-09-0*]) can be classified as a monoazamonomethineoxonol dye [352]:

The corresponding symmetrical dye, rubazonic acid [*909-59-1*], synthesized from phenylmethylpyrazolone and the corresponding unsymmetrical dyes containing the pyridone group should also be classified as monoazamonomethineoxonol dyes [353].

8.2. Trimethineoxonol Dyes and Higher Vinylogs

The reaction of cyclic α-ketomethylene compounds with β-alkoxyacroleins yields trimethineoxonol dyes [354]. With 3-cyano-1-ethyl-4-methyl-6-hydroxypyrid-2-one the following dye is obtained:

This dye is used in photography and in electrophotography for producing organic photo-

conductors [355]. The detection of lipoperoxides with thiobarbituric acid is based on the formation of a trimethineoxonol [356]. Pentamethinecyanineoxonol dyes are used in thermoreactive recording materials [357].

9. Methine Dyes with Betaine Structure

Condensation of squaric acid with two equivalents of a N,N-disubstituted aniline in the presence of a strong acid and a primary alcohol produces dyes with a betaine structure in the ground state. Their absorption maximum exceeds 600 nm [358].

[13458-60-1]

Condensation may also be performed in the presence of an alkylamine [359] and by azeotropic distillation of the water formed in the reaction [360].

Dyes substituted by halogen in the 2-position relative to the squaric acid are used in organic photoconductors for electrophotography [361]. Dyes with hydroxyl groups in this position are used to produce IR-sensitive recording materials [362]. Dyes in which the aniline nitrogen has a benzyl substituent have proved particularly useful in electrophotography [363].

Instead of aromatic amines, compounds with a reactive methylene group can also be used as condensation components. Dyes formed from 2,6-dimethyl-4-phenyl- and 2-methyl-4,6-diphenylpyrylium salts absorb in the IR region [364]. The following dye

absorbs at 862 and 912 nm. Dyes with a thiopyrylium terminal absorb in the same region [365]. The dyes are used to produce nonerasable optical discs. Dyes synthesized from squaric acid [366] and croconic acid [367] with azulenium terminal systems can be used for the same purpose.

10. Neutral Methine Dyes

In cationic and anionic methine dyes, the two heteroatoms at the ends of the methine chain can partially take up charge. The terminal atoms in neutrocyanines have different properties. The methine system includes both a donor (D) and an acceptor group (A). If a betaine structure is formed in the transition to the first electronically excited state, then the donor group carries the positive charge and the acceptor group the negative charge. Thus light absorption results in charge transfer.

In the industrially important dyes the *donor* is always an amino group. However, the donor may also be oxygen or sulfur. Under photoexcitation the free electron pair on nitrogen is transferred to the conjugated system with the formation of a positive charge at the nitrogen. The nitrogen may be bonded within an open chain or a ring:

In the most important industrial dyes the electron *acceptors* are carbonyl, thiocarbonyl, and nitrile groups. All three groups take up the negative charge in the first excited state

The acceptor group may also be a member of a ring.

The neutrocyanine dyes are insoluble in water and therefore must be dispersed if they are to be used in aqueous dye baths. They may however also contain hydrophilic groups (e.g., sulfonic acid or quaternary ammonium groups) and then acquire the character of cationic or anionic dyes with localized charge. In cationic and anionic methine dyes the charge is delocalized.

10.1. Enamineneutrocyanines

In the enamineneutrocyanines the amino group acting as the electron donor is coupled directly to the methine chain. *N*-vinylindole [368] and *N*-vinylcarbazole [369] can react with tetracyanoethylene to form enamineneutrocyanines. The compound

[31317-52-9]

is used as a photoconductor for electrophotographic applications.

10.2. Aminoarylneutrocyanines

The aminoarylneutrocyanine dyes are the phenylogs of the enamineneutrocyanines, an aromatic group being inserted between the donor amino group and the methine chain. Open-chain as well as cyclic compounds can be used as condensation components with reactive methylene groups.

10.2.1. Aminoarylneutrocyanines with Open-Chain Terminal Groups

Condensation of 4-dialkylaminobenzaldehydes with cyanoacetates or cyanoacetamides yields dyes that color cellulose esters, particularly cellulose acetate, brilliant greenish-yellow shades [370]. The following dye (Celliton Fast Yellow 7G, Telasol Yellow 4 GLS) is particularly suitable for dyeing cellulose acetate [371]:

[4361-84-6]

The lightfastness of these dyes on poly(ethylene glycol)terephthalate is only moderate and can be improved considerably if malononitrile is used as condensation component.

Dyes with short-chain alkyl substituents on the amino group tend to sublime from polyesters. This property is used to advantage, however, in transfer printing, especially in the transfer from paper to textile fabrics and in the production of colored copies by sublimation transfer printing [372]. For dyeing polyester fibers, various functional groups are introduced to reduce the sublimation.

Dyes in which the hydroxyethyl group on the nitrogen atom is esterified by aromatic carboxylic acids have a particularly good fiber affinity capacity [373]. An example is

[41284-31-5]

Commercial products are Resolin Brilliant Yellow 7GL (Bayer) and Serisol Brilliant Yellow 6GL (Yorkshire Chemical).

Esterification of the hydroxyethylamino group with isocyanates yields dyes with carbamate groups [374]. Commercial products include Foron Brilliant Yellow 6GFL, S-7GL (Sandoz), Palanil Yellow 7G (BASF), and Kayalon Polyester Light Yellow 6GSF (Nippon Kayaku). The stability of these dyes to hydrolysis in a neutral dye bath is increased by introducing aromatic groups. Aryl ethers [375], aryl thioethers [376] and benzothiazolyl thioethers [377] have been used as substituents. The following dye is stable in a dye bath up to pH 7:

[34613-03-1]

Commercial products are Amacron Yellow 6GSP (Koppers) and Proxester Brilliant Yellow 8GL (Protex).

Dyes that are bonded via the alkyl group of the aminoaryl nitrogen to a sterically hindered piperidine (radical quenchers) exhibit high lightfastness [378].

Dyes derived from 2,2,4,7-tetramethyltetrahydroquinoline and whose ethyl group in the 1-position is substituted with a carbamate group are industrially important [379]:

[63467-19-6]

Commercial products include Polycron Yellow 6GP (Holliday), Serilen Brilliant Yellow 6GLS (Yorkshire Chemical), and Sumikaron Yellow 7GTH (Sumitomo).

The above-mentioned dyes are used as the yellow component for producing colored copies in sublimation transfer printing (video printing) [380]. The more sublimation-fast representatives are especially useful; on account of the high energy density at the thermohead they are transferred from the colored ribbon onto the substrate but then do not diffuse out when the colored copy is stored.

Dyes with two separate chromophore systems are obtained from dialdehydes that are prepared by reacting *N*-hydroxyethyl- or *N*-chloroethyl-aminobenzaldehydes with bifunctional reactants. Coupling is preferably effected via ester groups [381]. The following dye

[25857-05-0]

colors polyester and cellulose acetate a brilliant greenish-yellow shade. Commercial products are Terasil Brilliant Yellow 6G and Cibacet Brilliant Yellow 6G (Ciba-Geigy).

Dyes obtained from *N*,*N*-bishydroxy-ethylaminobenzaldehydes and malononitrile are added before or during the polyaddition reaction used to produce polyurethanes. The dyes are bonded covalently to the polyurethanes and diffusion-fast colored foamed plastics are obtained [382]:

[25665-01-4]

The dyes can also be produced by hydrolyzing the corresponding bisacetoxy compounds [383].

Aminoarylneutrocyanines synthesized from cyanoacetates [384] or malonates [385] can be incorporated into bulk polyesters by condensation reactions.

A cyano substituent on the methine group produces an extremely strong bathochromic shift [386]. The following dye

colors polyester fibers a red-violet shade. In order to improve sublimation fastness, dyes with aryl ether [387] and heteroaryl thioether groups [388] in the aminoaryl group have been proposed. Dyes that are derived from tetrahydroquinoline are also industrially important [389]; they can be applied to polyester textiles by transfer printing [390]. These dyes are also used as red components (magenta) in sublimation transfer printing [391].

Dyes containing a N-heteroaryl group instead of the aminoaryl group are also suitable for dyeing polyester a brilliant greenish-yellow shade. Suitable heterocycles include pyridine and thiazole. The following tricyanovinyl dye is used as the red component in video printing:

[117555-60-9]

Suitable open-chain methylene compounds include cyanomethyl-substituted N-heterocycles, in particular 2-cyanomethylbenzimidazole [394] and 2-cyanomethyl-4-quinazolin-4-one [395]. On reaction with 4-dialkylaminobenzaldehydes, compounds are formed that dye polyester yellow:

[51553-32-3]

Other suitable condensation components include the cyanomethyl derivatives of 1,3,4-

thiadiazole [396], benzoxazole [397], and benzothiazole [398].

Coumarin Dyes. If the dialkylaminobenzaldehyde bears a hydroxyl group in the 2-position relative to the aldehyde group, ring closure between the hydroxyl and the cyano group occurs, with formation of a coumarin [399]:

[27425-55-4]

The resultant 3-heteroaryl-7-dialkylaminocoumarins have an intense fluorescent greenish-yellow color and are suitable for dyeing polyester, polyamide and cellulose acetate fibers [400] (→Fluorescent Dyes, Chap. 3.

Other heterocyclic substituents have also been incorporated at the 3-position of coumarin to produce fluorescent dyes (e.g., thiazole [401], benzothiazole, benzoxazole [402], quinazolin-4-one [403], 2*H*-1,2,4-benzothiadiazine-*S,S*-dioxide [404], 1,3,4-oxadiazole [405], and 1,3,4-thiadiazole [406]. All of these dyes color synthetic fibers an intensely fluorescent greenish-yellow shade. Coumarin compounds with a 7-alkoxy or 7-heterocyclic substituent absorb in the shorter wavelength region and have a blue fluorescence. They are used as optical brighteners [407] (→Optical Brighteners). The coumarin dyes include many important laser dyes (→Laser Dyes, Chap. 2.3.).

Coumarinimines are primary products of coumarin ring closure. Red fluorescent dyes are obtained by reaction with ethoxymethylenemalononitrile [408]. Condensation with malononitrile yields a dicyanomethylenechromene derivative [409]. If the heterocyclic substituent includes a free NH group, further ring closure with one of the cyano groups can take place to produce a pentacyclic ring system [410].

[52372-39-1]

This dye colors polyesters and thermoplasts red with an orange fluorescence.

Coumarin dyes that contain a cyclic methylene compound in the 2-position are obtained by a condensation reaction of β-dicarbonyl compounds, in which one of the carbonyl groups is part of a cyclic system, with dialkylaminosalicylaldehyde [411]. The following dye is obtained by reacting 3-methyl-1-phenyl-4-acetylpyrazol-5-one with 4-diethylaminosalicylaldehyde:

[71494-86-5]

This dye colors polyesters a brilliant yellowish-red shade.

Commercial Products. Setaron Brilliant Flavin 8GFF (Ciba-Geigy), Resolin Brilliant Yellow 10GN (Bayer), Foron Brilliant Flavin S8GF (Sandoz), Sumikaron Brilliant Flavin S-10GL (Sumitomo), Macrolex Fluorescence Yellow 10GN (Bayer), Fluorol Red BK, GK, and Palanil Luminous Red G (BASF).

Red 4-cyanocoumarin dyes with a strong orange to red fluorescence are obtained by addition of sodium cyanide to the 3,4-bond in coumarin, followed by oxidation with bromine or lead tetraacetate [412]. These dyes can be used in solar collectors [413]. 4-Cyanocoumarin compounds with a thiazole group in the 3-position have also been proposed for the same purpose [414]:

[70546-25-7]

The pentacyclic coumarin dyes described above can also be substituted by a cyano group at the 4-position of the coumarin system. These dyes color polyesters blue [415]. 4-Cyanocoumarin dyes with an alkoxy, sulfonamide, or heterocyclic group instead of the 7-dialkylamino group are yellow fluorescent dyes

that are used to dye plastics or in solar collectors [416].

Cationic Aminoarylneutrocyanines. Cationic aminoarylneutrocyanines contain a quaternary ammonium group bonded via an alkylene group. The positive charge is therefore not part of the mesomeric system. Dyes in which the quaternary ammonium group is bonded via an alkylene group to the aminoaryl nitrogen atom dye polyacrylonitrile in brilliant greenish-yellow shades. Coloring strength is substantially increased if the quaternary ammonium group is bonded to a cyanoacetate moiety [417]. The following dye is used to dye paper in greenish-yellow shades:

[64992-16-1]

Papers colored with such dyes can be fully bleached during recycling. Cationic charge may also be introduced by a cycloammonium group bonded via an ester group (e.g., the pyridinium [418] or imidazolium group) [419]. The commercial products are Astra Yellow 4G (Bayer), Basazol Yellow 46L, 47L, 51L (BASF), and Albright Yellow BR (American Color and Chem.).

Anionic Coumarin Dyes. Aminoarylneutrocyanine dyes that bear sulfonic acid groups are not sufficiently resistant to hydrolysis in the dye bath. This disadvantage does not apply to coumarin derivatives prepared from 2-hydroxy-4-dialkylaminobenzaldehydes. The following compound dyes polyamide in a fluorescent greenish-yellow shade [420]:

[56330-12-2]

The commercial product is Nylosan Brilliant Flavin E-8G (Sandoz).

Anionic coumarin dyes are also derived from 7-hydroxycoumarin. The anion fluoresces extremely strongly. 3-Benzoxazolyl-7-hydroxycoumarin and the corresponding sulfonic acid are used to produce counterfeit-proof papers [421]. The heteroaryl phosphates obtained from 3-benzimidazolyl-7-hydroxycoumarin on reaction with phosphorus oxychloride can be used for the fluorimetric determination of phosphatase activity in physiological systems [422].

Vinylogous Aminoarylneutrocyanines. The condensation of dialkylaminocinnamaldehydes with malononitrile, cyanoacetates, or benzenesulfonyl acetonitrile yields dyes suitable for dyeing polyester or cellulose acetate. Dyes with a substituted trimethine chain are synthesized by reacting benzonitrile with acetonitrile in the presence of sodium amide to form a ketimine. The latter is reacted with malononitrile to yield the dicyanomethylene compound which is in turn reacted with dialkylaminobenzaldehydes. The resulting dye is used to dye textile fibers and plastics, and also as a sensitizer in electrophotography [423]:

[106577-47-3]

7-Dialkylaminocoumarin-3-aldehyde, which can be obtained by the Vilsmeier reaction of 7-dialkylaminocoumarin, should be regarded as a ring closure derivative of the corresponding dialkylaminocinnamaldehyde. The coumarin aldehyde produces a brilliant greenish-yellow shade in transfer printing on polyester [424]. Condensation of the aldehyde with malononitrile yields a dye that colors polyester in brilliant fluorescent scarlet shades [425]:

[57818-82-3]

A brilliant greenish-yellow dye is obtained with benzoyl hydrazide [426], and a red fluorescent dye with cyanomethylbenzoxazole [427]. The vinylogs of these compounds are obtained by the Vilsmeier reaction of 3-acetylcoumarins

and reaction with compounds containing a reactive methylene group [428].

10.2.2. Aminoarylneutrocyanines with Cyclic Terminal Groups

Compounds that dye polyesters yellow to orange are obtained by the condensing dialkylaminobenzaldehydes with 1,2-diarylpyrazolidin-3,5-dione [429]. The following dye

is used as the yellow component for producing colored copies in sublimation transfer printing (video printing) [430]. The products obtained from dialkylaminobenzaldehydes and 1-phenyl-3-dialkylaminopyrazol-5-one may also be used for the same purpose [431]. Replacement of the methine hydrogen atom by a cyano group yields a magenta dye for sublimation copying [432]. Yellow dyes that are used in the charge-generating layer of organic photoconductors are obtained by reaction of dialkylbarbituric acid with aminobenzaldehydes [433]. Here too the methine hydrogen atom can be replaced by the cyano group to produce dyes suitable for dyeing polyester [434]. If *N*-benzoylaminoacetic acid is condensed with terephthaldehyde, an azlactone dye is formed that dyes polyester a fluorescent yellow [435].

A new class of aminoarylneutrocyanine dyes absorbs at particularly long wavelengths due to the dicyanomethylene group in the cyclic terminal system. The compound synthesized from 2-methyl-4-dihexylaminobenzaldehyde and 3-dicyanomethylenebenzothiophene *S,S*-dioxide dyes polyester a brilliant blue shade and has good lightfastness [436]:

[*122533-66-8*]

Dimeric dyes formed from aminobenzaldehydes coupled via an alkylene bridge have high sublimation fastness [437]. 1-Methyl-2-phenylindole-3-aldehyde produces a red-violet shade in the same dye series [438]. Aminobenzaldehydes containing sulfonic acid groups condense with 3-d ic ya no me th yl en eb en zo th io ph en e-*S,S*-d io x-ide to give blue polyamide dyes [439]. The commercial products are Foron Brilliant Blue S-R (Sandoz) and Kayalon Polyester Brilliant Blue FR-S (Nippon Kayaku).

Pyrrole dyes with an exocyclic methylene group are formed by condensation of dialkylaminobenzaldehydes with dimeric malononitrile, replacement of the methine hydrogen atom by a cyano group, and ring closure [440]:

[*112304-76-4*]

These dyes color polyester a brilliant blue shade. They can also be synthesized by reacting 1-alkyl-3-c hl or o-4-c ya no-5-d ic ya no me th yl en ep yr ro li d-2-one with aromatic amines [441]. The dyes are suitable for sublimation thermotransfer printing [442]. Commercial products are Kayalon Polyester Brilliant Blue F2B-S and Kayalon Polyester Blue-Green FG-S (Nippon Kayaku).

Aminoarylazaneutrocyanines. These dyes can be synthesized from 4-nitroso-*N,N*-dialkylanilines and 1-phenyl-3-methylpyrazol-5-one:

[*4719-52-2*]

They may be used as sublimable dyes for transfer printing [443] and for organic photoconductors used in electrophotography [444].

10.3. Merocyanine Dyes

In merocyanine dyes the nitrogen atom acting as electron donor is part of a heterocyclic ring. The terminal acceptor group may either be in an open chain or a member of a ring.

10.3.1. Merocyanine Dyes with Open-Chain Terminal Groups

If N-heterocyclic carbonyl compounds are condensed with derivatives of cyanoacetic acid, zeromethine dyes are formed. The vinylogous dimethineneutrocyanine dyes are obtained by condensation of the N-heterocyclic methylene-ω-aldehydes with cyanoacetic acid derivatives.

Zeromethine Dyes. If N-alkylnaphtholactam is condensed with cyanoacetic acid derivatives (e.g., malononitrile) in the presence of acid condensation agents, yellow disperse dyes are obtained that dye polyester, polyamide, and polyacrylonitrile in brilliant, lightfast shades [445]. The following dye

[57232-94-7]

is used in transfer printing [446]. If a thiophenyl group is introduced in the 4-position to the naphtholactam nitrogen atom, the color shifts to a brilliant orange shade. Additional ring closure results in a violet dye for dyeing polystyrene [447]. Five- and six-membered N-heterocycles with cyanomethyl substituents can be condensed with naphtholactam and N-alkylnaphtholactams to give orange and red dyes. With the thiophenyl group in the 4-position of the naphthalene ring, red dyes for polyester materials are obtained by reaction with 2-cyanomethylbenzothiazole. Additional ring closure yields a reddish-blue dye [448]:

Other suitable starting materials are the cyanomethyl compounds of 1,3,4-oxadiazole [449] and quinoxalinone [450]. Dyes synthesized from naphtholactam and 2-cyanomethylbenzothiazole and containing sulfonic acid groups form zinc complexes that are suitable for spin dyeing polyamide in fluorescent red shades [451].

The zeromethinemerocyanines also include pigments obtained by reaction of aminoiminoisoindolenine with cyanoacetamides. These lightfast yellow pigments are used in paints, lacquers, and plastics [452]. Heat-stable red pigments for coloring polystyrene are obtained with cyanomethylbenzimidazole [453].

Dimethinemerocyanine Dyes. Dimethinemerocyanine dyes are obtained by condensation of 1,3,3-trimethyl-2-methyleneindoline-ω-aldehydes with cyanoacetates or malononitrile in the presence of alkaline catalysts. The yellow dyes are suitable for dyeing synthetic fibers. Introduction of a carboxylate group at the 5-position of the indoline moiety produces dyes that are very lightfast on polyamide fibers [454]:

[99750-70-6]

These dyes are also suitable for transfer printing on polyester and polyamide textiles [455].

Neutrocyanine dyes whose methine chain contains a cyano substituent are obtained if 1,3,3-trimethyl-2-cyanomethyleneindoline derivatives are formylated according to the Vilsmeier reaction and then reacted with malononitrile [456]. The dyes can also be obtained by reacting 1,3,3-trimethyl-2-methyleneindoline with tetracyanoethylene [457]. A

commercial product is Resolin Brilliant Yellow P8GLN (Bayer).

10.3.2. Merocyanine Dyes with Cyclic Terminal Groups

These dyes include sensitizers (→Photography) and textile dyes.

Zeromethinemerocyanine Dyes. With acid condensation agents (e.g., phosphorus oxychloride) naphtholactam is converted into the 2-halogen derivative and can then be condensed with compounds containing a reactive methylene group to form zeromethinemerocyanine dyes. Dyes synthesized from naphtholactam and N-alkylated barbituric acids produce lightfast, sublimation-fast yellow dyeings on polyester [458]:

Thioaryl substitution in the 4-position to the naphtholactam nitrogen atom produces a brilliant scarlet shade [459]. If a carboxylate group is introduced into the 4-position relative to the naphtholactam carbonyl group, then condensation with pyrazolones or barbituric acids yields red disperse dyes [460]. A polynuclear heterocycle, in which the partial structure of barbituric acid is recognizable is obtained by reaction of 2-cyanomethylbenzimidazole with isocyanates followed by ring closure. Condensation with naphtholactam yields a dye which dyes polystyrene a brilliant, lightfast scarlet shade [461]:

[77365-28-7]

The corresponding compounds with a fused benzothiazole structure dye polystyrene a brilliant red [462]. Red dyes for plastics are also obtained from naphtholactam and derivatives of 1-alkyl-2-hydroxypyrid-6-one [463]. Condensation of naphtholactam with 4-hydroxycoumarin cannot be performed with phosphorus oxychloride because the hydroxyl group is replaced by chlorine. The alternative route via the 4-morpholinoenamine, which condenses with naphtholactam to prepare dyes that color polyester in brilliant fluorescent yellow, orange, and red shades, is therefore employed [464]:

R = H: yellow [65626-20-2]
R = Br: orange [65625-85-6]
R = SC_6H_5: red [65626-05-3]

The zeromethinemerocyanines also include pigments that are obtained by condensation of aminoiminoisoindolenine with cyclic compounds containing a reactive methylene group. Derivatives of barbituric acid [465] and pyrazolone [466] are preferably used. The dye

[36888-99-0]

is a brilliant yellow pigment used for coloring poly(vinyl chloride), polyethylene, and paints.

Quinophthalone Dyes. Quinophthalones are a particularly important class of zeromethinemerocyanine dyes [467]. They take their name from the oldest member of this series, which was prepared by E. Jakobsen in 1882 by melting phthalic anhydride with the quinaldine-containing quinoline bases from coal tar. The dye exists in the tautomeric form that is stabilized by hydrogen bonds:

[83-03-9] [83-08-9]

The unsubstituted dye was marketed as alcohol-soluble Quinoline Yellow (C.I. 47 000) and was used for coloring wax, paraffin, and alcoholcontaining paints. The sulfonated dye (C.I. 47 005) was previously widely used for wool, silk, and paper dyeing as well as in the graphics industry. Quinoline Yellow KT (C.I. 47 035) is the sulfonated quinophthalone of 5,6-benzoquinaldine and phthalic anhydride [468].

The benzothiazole-substituted quinaldine obtained from dehydrothiotoluidinesulfonic acid was condensed with phthalic anhydride to give a quinophthalone dye that is marketed by Bayer as Levacell Brilliant Yellow 5G for dyeing paper. Condensation in the presence of quinoline yields a purer dye in higher yield [469].

The lightfastness of the dyes is considerably improved by introducing a hydroxyl group into the 3-position of the quinoline system, because the system is stabilized by a further hydrogen bond [470].

[*7576-65-0*]
C.I. Disperse Yellow 54

3-Hydroxyquinophthalone, produced by G. Kranzlein in 1934 as a precursor for Supra Light Yellow GGL, proved to be an excellent dye for dyeing poly(ethylene terephthalate) and plastics in bulk. The compound is obtained by condensation of 2-methyl-3-hydroxyquinoline-4-carboxylic acid with phthalic anhydride and decarboxylation. Particularly pure dyes are obtained if the conversion is carried out in N,N-dialkylanilines as solvent [471].

The *commercial products* of Disperse Yellow 54 (C.I. 47 020) are as follows: Palanil Yellow 3GE, Thermoplast Yellow 066 (BASF), Samaron Yellow 3GL (Hoechst), Terasil Yellow 2GW, Teraprint Yellow 2G (Ciba-Geigy), Resolin Yellow 4GL (Bayer), Dianix Yellow 3G-E (Mitsubishi), Kayaset Yellow A-G (Nippon Kayaku), Miketon Polyester Yellow F3G (Mitsui), Seriplas Yellow 3GL (Yorkshire Chemical), Sumiplast Yellow HLR (Sumitomo), Vondispers Yellow A-3G (Vondelingenplaat), and Waxoline Yellow 3GP-FW (ICI).

3-Hydroxyquinophthalone and its substitution products are used as yellow components in transfer printing on polyester textiles as well as for producing colored copies in sublimation transfer printing [472]. A wool dye of outstanding lightfastness is obtained by sulfonation of 3-hydroxyquinophthalone. Commercial products are Basovit Yellow 095E (BASF) and Quinoline Yellow 70 (Hoechst).

The wet fastness and sublimation fastness of 3-hydroxyquinophthalone can be improved by a halogen substituent. Pure 4-bromo-3-hydroxyquinophthalone is obtained by reaction of 3-hydroxy-quinophthalone with bromine in 80 – 100 % sulfuric acid at low temperature (C.I. Disperse Yellow 64) [*10319-14-9*] [473]. In dilute sulfuric acid, however, bromine reacts at 100 – 105 °C to form more highly brominated compounds [474].

The *commercial products* of C.I. Disperse Yellow 64 are as follows: Samaron Yellow H3GL (Hoechst), Palanil Yellow 3G, Thermoplast Yellow 103 (BASF), Resolin Yellow 3GL (Bayer), Foron Yellow SE-3GL (Sandoz), Dianix Yellow HG-SE (Mitsubishi), Kayacelon Yellow E-3GL (Nippon Kayaku), Miketon Polyester Yellow RSE (Mitsui), and Serilen Yellow V4GL (Yorkshire Chemical).

Ethers and thioethers of 3-hydroxyquinophthalone are obtained by reaction of 4-halogen-3-hydroxyquinophthalones with aliphatic, araliphatic, or aromatic hydroxy or thio compounds [475]. A commercial product is Thermoplast Yellow R (BASF).

An ether group can also be introduced by using 4-hydroxyphthalic anhydride as condensation component and subsequently etherifying the hydroxyl group. Etherification with halides of 1,3,5-triazine followed by replacement of one or both halogen atoms by aliphatic amines yields dyes that are suitable for dyeing textiles containing both cotton and synthetic fibers [476]. The triazine ether group may also be bonded to the quinophthalone dye via a carboxylic acid anilide group [477].

Alkanesulfonates and in particular benzenesulfonates of 4-hydroxyphthalic anhydride yield, when reacted with 3-hydroxyquinaldine-

4-carboxylic acid, sublimation-fast, yellow dyes with high affinity for polyesters [478]. Sulfonates and sulfonamides of quinophthalone are obtained from the corresponding sulfochloride by reaction with phenols [479] and aliphatic amines [480]. They are sublimation-fast dyes with high affinity for polyesters.

Quinophthalone dyes with a carboxyl substituent in the carbocyclic ring system are obtained by condensation of trimellitic anhydride with 3-hydroxyquinaldine-4-carboxylic acid. A particularly suitable solvent for this reaction is sulfolane; the dye can be esterified at the carboxyl group without intermediate separation [481]. The dyes are suitable for dyeing polyester and for producing colored copies in sublimation transfer printing [482]. A commercial product is Sumikaron Yellow SE-RPD (Sumitomo).

Quinophthalone dyes synthesized from benzenetetracarboxylic acid, whose free carboxyl groups are esterified by long-chain alkyl groups, are used in liquid crystal displays [483]. Quinophthalone dyes have also been prepared from naphthalene-2,3-dicarboxylic acid [484]. Commercial products are Dialight Yellow GRM and Diaresin Yellow 5110 (Mitsubishi).

Introduction of cationic substituents yields watersoluble dyes that dye paper in brilliant yellow shades with good lightfastness. The cationic groups are introduced by reacting quinophthalone dyes with formaldehyde and 1-alkylimidazole [485] or by condensing with chloroacetylmethylolamide (Einhorn reaction), the chlorine being replaced by pyridine [486].

Quinophthalones synthesized from tetrachloro- or tetrabromophthalic anhydride and derivatives of quinaldine are suitable for dyeing plastics (e.g., polyolefins, polystyrene, polyacrylates) [487].

8-Aminoquinaldine is particularly suitable for producing pigments because it can react with 2 mol of tetrachlorophthalic anhydride. The amino group forms an imide, and the methyl group reacts to form the quinophthalone [488]. 8-Aminoquinaldine can also be converted into the imide with naphthalic acid prior to reaction with tetrachlorophthalic anhydride [489].

A particularly suitable starting material for producing pigments is 3-hydroxyquinophthalone carboxyloyl chloride. Reaction with aromatic mono- or diamines gives pigments that dye poly(vinyl chloride) yellow with good migration fastness and lightfastness [490].

Condensation of pyromellitic anhydride (1,2,4,5-benzene tetracarboxylic acid anhydride) with equimolar amounts of a quinaldine yields quinophthalone dicarboxylic acids which, after conversion into the anhydride, can react to form dyes containing imide groups. Monoamines yield pigments for paints and printing inks [491]:

[58130-76-0]

Diamines such as 1,4-diaminobenzene [492], 2,6-diaminonaphthalene [493], 4,4'-diaminodiphenylsulfone [494], and dichlorobenzidine [495] yield migration-stable yellow pigments for dyeing poly(vinyl chloride).

Mixed quinophthaloneisoindolenine pigments are obtained by reaction of 8-aminoquinaldine with aminoisoindolenine derivatives, followed by condensation with tetrachlorophthalic anhydride. The following pigment dyes poly(vinyl chloride) a lightfast and migration-fast orange shade [496]:

Dimethineneutrocyanine Dyes. Neutrocyanine dyes suitable as the yellow component for producing colored copies in sublimation transfer printing are obtained by reaction of 1,3,3-trimethyl-2-methyleneindoline-ω-

aldehyde with 1-phenyl-3-methylpyrazol-5-one [497] and 1-phenyl-3-dimethylaminopyrazol-5-one [498]. The lightfastness of these dyes on polyamide is significantly improved by introducing a carboxylate group at the 5-position of the indole moiety [499]:

[5718-26-3]

The dye is also suitable for the transparent dyeing of polystyrene and poly(methyl methacrylate) in brilliant orange shades [500]. Reaction of 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde with 1-alkyl-3-cyano-4-methyltetrahydropyridine-2,6-dione produces brilliant red shades with poly(ethylene terephthalate) [501]. Dimethineneutrocyanines with benzothiazole and quinaldine as heterocyclic terminal system are used as organic photoconductors in electrophotography [502].

Dimethineneutrocyanine dyes from cyclic compounds with a reactive methylene group bearing a dicyanomethylene group absorb at long wavelengths. The compound synthesized from 1,3,3-trimethyl-2-methyleneindoline-ω-aldehyde and 3-dicyanomethylenebenzothiophene *S,S*-dioxide dyes polyester a reddish-blue shade [503]:

[115281-48-6]

Dyes of this series are also suitable for producing nonerasable discs for optical information recording [504].

1. Introduction

Monomethylamine [*74-89-5*], methanamine, aminomethane, CH_3NH_2, M_r 31.06; dimethylamine [*124-40-3*], *N*-methylmethanamine, $(CH_3)_2NH$, M_r 45.08; and trimethylamine [*75-50-3*], *N,N*-dimethylmethanamine, $(CH_3)_3N$, M_r 59.11, are colorless gases at room temperature. All three are produced by the reaction of methanol and ammonia over solid acid catalysts.

Methylamines are the simplest members of the amine family and constitute an economical source of reactive amino nitrogen. Methylamines are valuable for the synthesis of a broad range of products applicable in such diverse fields as medicine, agriculture, rubber, plastics, and synthetic fibers.

Methylamines display chemical reactivity typical of small aliphatic amines. They bear a strong resemblance to ammonia from which they are derived, and their physical properties largely parallel those of ammonia.

Even at concentrations as low as 0.1 ppm in air, methylamines have a distinct, offensive, fishy odor. At higher concentrations, their odor is more ammoniacal.

2. Physical Properties

The most important physical properties of methylamines are listed in Table 1. Table 2 summarizes the physical properties of aqueous methylamine solutions [1], [2].

3. Chemical Properties (→ Amines, Aliphatic, Chap. 2.)

All three methylamines readily form salts with acids (e.g., mono-, di-, or trimethylammonium halides–also known as the corresponding amine hydrohalides–with the hydrohalic acids). Reaction with alkyl halides leads to further alkylation, up to and including the formation of quaternary ammonium salts, $R_{4-n}(CH_3N)_n{}^+X^-$ (e.g., methylethylamine, methyldiethylamine, and methyltriethylammonium halide in the reaction of ethyl halide with monomethylamine).

Reaction of mono- or dimethylamines with carboxylic acids and their derivatives results in *N*-methylamides. Similarly, substituted mono- and dimethylsulfonamides can be prepared by treatment with a sulfonyl chloride.

Monomethylamine (MMA) reacts with phosgene to produce methyl isocyanate, with carbon disulfide in the presence of sodium hydroxide to give sodium monomethyldithiocarbamate, and with urea to give *N*-methylurea via the intermediate ammonium cyanate. A mixture of chloroform and alkali converts monomethylamine to methyl isonitrile. Alkaline hypochlorites lead to a mixture of methylmono- and dichloroamines. Monomethylamine is decomposed by nitrous acid to methanol and nitrogen, and by nitrosyl chloride to methyl chloride and nitrogen. Ethylene oxide reacts with monomethylamine to produce methylethanolamine and methyldiethanolamine.

Dimethylamine (DMA) and phosgene react to produce tetramethylurea. Reaction with carbon disulfide and alkali in this case gives an

alkali dimethyldithiocarbamate, whereas urea leads to the expected *N,N*-dimethylurea. Both nitrous acid and nitrosyl chloride convert dimethylamine to the corresponding nitrosamine. Ethylene oxide reacts with dimethylamine to give dimethylethanolamine.

Oxidation of *trimethylamine* (TMA) with hydrogen peroxide or a peracid gives trimethylamine oxide. The reaction with ethylene oxide in this case yields choline. Trimethylamine can form quaternary ammonium compounds by *N*-alkylation.

4. Production

4.1. Synthesis

Methylamines are prepared commercially by the exothermic reaction of methanol with ammonia over an amorphous silica – alumina catalyst at 390 – 430 °C. All three possible methylamines are produced. The reaction proceeds to thermodynamic equilibrium, whose position is governed by the temperature and the nitrogen – carbon ratio as shown in Figure 1 [3], [4].

The equilibrium composition favors the formation of trimethylamine, whereas market demand is greater for mono- and especially dimethylamine. Excess mono- and trimethylamines are recycled over the same catalyst, leading to additional dimethylamine by dismutation or disproportionation.

The kinetics of the overall reaction have been studied by using several amorphous solid acid catalysts [5], [6]. Amine synthesis can be modeled by six bimolecular equilibrium reactions, three involving amine synthesis and three describing dismutation:

Amination reactions

$$NH_3 + CH_3OH \rightleftharpoons CH_3NH_2 + H_2O$$

$$(CH_3)_2NH + CH_3OH \rightleftharpoons (CH_3)_3N + H_2O$$

Dismutation reactions

$$CH_3NH_2 + CH_3NH_2 \rightleftharpoons (CH_3)_2NH + NH_3$$

$$CH_3NH_2 + (CH_3)_2NH \rightleftharpoons (CH_3)_3N + NH_3$$

$$(CH_3)_2NH + (CH_3)_2NH \rightleftharpoons (CH_3)_3N + CH_3NH_2$$

All six equilibrium constants are known [3], [7]. A parallel reaction leads to the formation of dimethylether, which may also be an intermediate in the synthesis of the amines:

$$2\,CH_3OH \rightleftharpoons CH_3{-}O{-}CH_3 + H_2O$$

Research has been directed toward improving the selectivity for dimethylamine through the use of shape-selective zeolite catalysts [8–16].

Figure 1. Composition of an equilibrium mixture of methylamines as a function of the nitrogen – carbon ratio at 350, 400, and 450 °C
a) Ammonia; b) Trimethylamine; c) Dimethylamine; d) Monomethylamine

Reactant selectivity is a consequence of one of the reactants being too large to pass through the zeolite channels, whereas *product selectivity* is observed when only certain products are of the proper size and shape to diffuse out of the channels [17]. The activity of zeolites with respect to the conversion of methanol is much higher than that of amorphous silica – alumina, but coke formation within the catalyst pores limits catalyst life even at 300 °C (instead of 400 – 430 °C used with amorphous silica – alumina catalysts) [18].

4.2. Purification

The crude reaction mixture consists essentially of excess ammonia; mono-, di-, and trimethylamines; reaction water; and unconverted methanol. Purification is generally effected in a train of four to five distillation columns.

In one technique (Fig. 2) the operating pressures of the columns are chosen in such a way that the top condensors can be cooled by standard 30 °C cooling water, and that the bottom reboilers are fed with saturated steam of about 195 °C. The first column (a) (known as the ammonia column), which operates at 1.7 MPa, removes excess ammonia. The latter is recycled to the synthesis section. In the second column (b), pure trimethylamine is recovered overhead by using extractive distillation with water and a pressure of 1.0 MPa. Extraction water, reaction water, and unconverted methanol are removed from the bottom of the third column (c); the mixture of mono- and dimethylamines is distilled overhead. This mixture is separated in the fourth distillation column (d) at 0.7 MPa, MMA being the overhead and DMA the bottom product.

In another technique, (Fig. 3), a supplementary column (b) operating at 0.7 – 0.9 MPa is inserted after the ammonia column (a) for bottoms removal of reaction water, certain impurities,

Figure 2. Schematic of methylamine purification
a) Ammonia column; b) Extractive distillation column; c) Column for water removal; d) MMA and DMA product column

and unconverted methanol. Most of the extraction water may be recycled; the small remaining quantity of bottom water, containing some impurities and methanol, is disposed of easily either by incineration or biological treatment.

5. Environmental Protection

Analysis of intermediate byproducts and final products occurs automatically in the operations control room with the aid of an on-line chromatographic analyzer coupled to an on-line computer. Centralizing the data handling in this way assures safe plant operation.

Two effluents are formed in the process:

1) gas containing amines and various byproducts (H_2, CO, N_2, O_2, ethylene), which is incinerated at high temperature to avoid formation of nitrosoamines; and
2) aqueous wastes, whose nature depends on the selectivity and activity of the catalysts. These aqueous solutions contain unconverted methanol and longer chain alkylamines, and can be treated by biological degradation with activated sludge.

6. Quality Specifications

Product purity as determined by gas chromatography is high ($>99\,\%$). Commercial methylamines must be free of higher chain alkylamines. Tables 3, 4, 5 provide typical commercial specifications.

Table 3. Specifications for monomethylamine

	Anhydrous	Aqueous solution
Monomethylamine, %	min. 99.2	min. 40
Di- and trimethylamine, %	max. 0.5	max. 0.2
Ammonia, %	max. 0.05	max. 0.02
Methanol, %	max. 0.1	max. 0.05
Water, %	max. 0.3	balance

7. Storage and Transportation

Methylamines are sold as anhydrous compressed liquefied gases and as aqueous solutions. They are extremely flammable products that should be stored in a well-ventilated area and protected from fire risk.

Monomethylamine. The hazard classifications for anhydrous monomethylamine are as follows:

ADR/RID	Class 2, no. 3 bt; labels no. 3 + 6.1, flammable; orange panel 236/1061
	Class 2, D 2200
UN no.	1061

whereas 40 % aqueous solutions of monomethylamine are classified as

ADR/RID	Class 3, no. 22 a/b; labels no. 3 + 8, flammable, caustic; orange panel 338/1235
IMDG Code	Class 3.1, D 3152
UN no.	1235

Figure 3. Methylamine purification with supplementary column
a) Ammonia column; b) Supplementary column; c) Extractive distillation column; d) Column for water removal; e) MMA and DMA product column

Table 4. Specifications for dimethylamine

	Anhydrous	Aqueous solutions	
		40 %	60 %
Dimethylamine, %	min. 99.5	min. 40.0	min. 60.0
Mono- and trimethylamine, %	max. 0.3	max. 0.15	max. 0.2
Ammonia, %	max. 0.02	max. 0.01	max. 0.01
Methanol, %	max. 0.1	max. 0.05	max. 0.05
Water, %	max. 0.2	balance	balance

Dimethylamine. Anhydrous dimethylamine must be classified according to

ADR/RID	Class 2, no. 3 bt; labels no. 3 + 6.1, flammable; orange panel 236/1032
IMDG Code	Class 3.1, D 3152
UN no.	1235

The hazard classification for aqueous solutions containing > 40 % DMA are

ADR/RID	Class 3, no. 22 a/b; labels no. 3 + 8, flammable, caustic; orange panel 338/1160
IMDG Code	Class 3.1, 3.2, D 3275
UN no.	1160

Table 5. Specifications for trimethylamine

	Anhydrous	Aqueous solution
Trimethylamine, %	min. 99.0	min. 45
Mono- and dimethylamine, %	max. 0.3	max. 0.15
Ammonia, %	max. 0.1	max. 0.05
Methanol, %	max. 0.1	max. 0.05
Water, %	max. 0.5	max. 0.25

Trimethylamine. Hazard classifications for anhydrous trimethylamine are as follows:

ADR/RID	Class 2, no. 3 bt; labels no. 3 + 6.1, flammable; orange panel 236/1083
IMDG Code	Class 2, D 2256
UN no.	1083

For an aqueous solution of ≤ 30 % trimethylamine, the following hazard classifications are used:

ADR/RID	Class 3, no. 22 a; flammable, caustic
IMDG Code	Class 3.2, D 3413
UN no.	1297

8. Uses

Monomethylamine is an intermediate in the synthesis of pharmaceuticals (e.g., theophylline), pesticides (carbaryl, sodium metham, carbofuran), surfactants, photographic develop-

ers, explosives, and solvents such as *N*-methyl-2-pyrrolidone.

Dimethylamine is also a synthetic intermediate. Examples of products based on dimethylamine include fungicides and rubber accelerators [zinc bis(dimethyldithiocarbamate) (Ziram), tetramethyl thioperoxydicarbonic diamide (TMTD), tetramethyl thiodicarbonic diamide (MTMT)], the propellant 1,1-dimethylhydrazine, various pharmaceuticals, monomers such as dimethylaminoethyl methacrylate, solvents (*N,N*-dimethylformamide, *N,N*-dimethyl- acetamide), catalysts [e.g., 2,4,6-tris[(dimethylamino)methyl]phenol (DMP 30)], the insecticide dimefox, surfactants, and ion-exchange resins.

Trimethylamine is used in the manufacture of choline salts, cationic starches, disinfectants, flotation agents, intense sweeteners, and ion-exchange resins.

9. Economic Aspects

Table 6 lists the principal manufacturers of methylamines by country, together with summary data on production capacity. The global market breakdown for methylamines is estimated to be 24 % MMA, 57 % DMA, and 19 % TMA [19].

10. Toxicology and Occupational Health

All gaseous amines are regarded as hazardous materials. At high airborne concentration, their odor resembles that of ammonia and the methylamines display an asphyxiating character. At lower concentration, they induce severe irritation and damage to the eyes and respiratory tract; skin contact results in burns. The slightest leak is easily recognized due to the characteristic fishy odor of the compounds, which is detectable above 0.1 ppm by volume. The TLV and the MAK value are 10 ppm (13 mg/m^3) by volume.

Monomethylamine (RTECS 1.1.78 – 31.1.87, NIOSH PF 6 300 000)

LD_{50} (mouse, inhalation): 2400 mg/m^3 over 2 h

Effects on skin (guinea pig): severe irritant at a dose of 100 mg (Draize test)

Dimethylamine (RTECS 1.1.78 – 31.1.87, NIOSH IP 8 750 000)

LD_{50} (rat, oral): 698 mg/kg

LC_{50} (rat, inhalation): 4540 ppm over 6 h

Toxic effects on eyes, respiratory system, and pulmonary system

Trimethylamine (RTECS 1.1.78 – 31.1.87, NIOSH PA 0 350 000)

LD_{50} (rat, inhalation): 3500 ppm over 4 h

1. Introduction

Methyl *tert*-butyl ether, 2-methoxy-2-methylpropane (MTBE) [*1634-04-4*], M_r 88.15, was first synthesized (by the classical Williamson ether synthesis) and characterized in 1904 [1].

Methyl *tert*-butyl ether (MTBE)

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a16_543

Extensive studies in the United States during World War II demonstrated the outstanding qualities of MTBE as a high-octane fuel component [2]. Even so, it was not until 1973 that the first commercial plant went on stream in Italy.

Reduction of the lead content in gasoline in the mid-1970s led to a drastic increase in demand for octane enhancers, with MTBE being used increasingly in this role. Political decisions about gasoline quality (e.g., lower aromatics content, lower vapor pressure and a defined oxygen content) especially in the United States had led to a significant increase in MTBE consumption in the 90th. In 1997 the world wide MTBE production reached some 19×10^6 t [44]. After years with two-digit growth rates (1990 – 1995) the increase in MTBE consumption is expected to be less than 2 % per year in the near future.

Table 1. Selected physical properties of MTBE

2. Physical and Chemical Properties

Physical Properties. Methyl *tert*-butyl ether is a colorless, readily mobile liquid with a characteristic terpene-like odor. Its most important physical properties are listed in Table 1:

Vapor pressure, density, and solubility in water, as well as the composition and boiling points of azeotropes with water and methanol, are given in Tables 2 and 3 [3]. Methyl *tert*-butyl ether has unlimited miscibility with all ordinary organic solvents and all hydrocarbons.

Chemical Properties. Methyl *tert*-butyl ether is very stable under alkaline, neutral, and weakly acidic conditions. In the presence of strong acids, it is cleaved to methanol and isobutene. Depending on reaction conditions the latter can form isobutene oligomers.

3. Resources and Raw Materials

MTBE is produced by the reaction of isobutene, contained in C_4-fractions, and Methanol. At present, *isobutene* from the following sources is used as feedstock for MTBE production [45]:

1) isobutene in raffinate 1, which is formed as a coproduct of butadiene production from steam cracker C_4 fractions (see Table 4 for typical composition).
2) pseudoraffinate 1, which is obtained by selective hydrogenation of butadiene in mixed C_4 fractions from steam crackers (composition, see Table 4)
3) isobutene contained in the C_4 fraction of fluid catalytic crackers (FCC – C_4's; for typical composition, see Table 4). FCC – C_4 is used as feedstock for ca. 29 % of MTBE production

Table 2. Vapor pressure, density, and water miscibility of MTBE

Temperature, °C	Vapor pressure, ∗ kPa	Density, kg/m^3	Miscibility

4) isobutene from dehydrogenation of isobutane, which is obtained both from refineries and from field butanes after isomerization (35 % of MTBE feedstocks); and
5) isobutene by dehydration of *tert*-butanol, a coproduct of propylene oxide synthesis (Halcon/Arco process, see → Propylene Oxide) (ca. 15 % of MTBE feedstocks)

Table 3. Binary azeotropes with MTBE

Azeotrope	*bp*, °C	MTBE content, wt %
MTBE – water	52.6	96∗
MTBE – methanol	51.6	86
MTBE – methanol (1.0 MPa)	130	68
MTBE – methanol (2.5 MPa)	175	54

∗ Condensate separates into two phases.

Raffinate 1 and pseudoraffinate 1 provide isobutene for approximately 21 % of world's total MTBE production [46].

Table 4. Typical composition of C_4 hydrocarbon streams from steam crackers (raffinate 1) and fluid catalytic crackers (FCC – C_4)

Compound	Raffinate 1, wt %	Pseudoraffinate 1, wt %	FCC – C_4, wt %
Isobutane	4	2	36
n-Butane	12	7.5	13
Isobutene	44	24	15
Butene-1	24	39	12
cis-Butene-2	6	8	9
trans-Butene-2	9	19	14
Butadiene-1,3	0.5	0.0	0.3
Balance	0.5	0.5	0.7

As demand for MTBE increases, the first source to be exploited will probably be free FCC – C_4 reserves. Any further expansion – and this also holds for the raffinate 1 route – is thus tied to new cracker construction. Field butanes will grow more than proportionally in importance. The relative share of *tert*-butanol as an isobutene source for MTBE production, on the other hand, is expected to decline because it is formed as a coproduct and thus linked to future propylene oxide demand. Raffinate 1 and FCC – C_4 can be utilized directly in MTBE synthesis. By contrast, isobutane must be dehydrogenated. The same holds true for field butanes after isomerization of the *n*-butane fraction to isobutane. A number of industrial processes have been established during the last decades [4], [47]. For the primary butane isomerization, the Butamer process is most commonly used. For the isobutane dehydrogenation, the commercially available processes Oleflex (UOP), Catofin (ABB Lummus Crest, Inc.), STAR (Phillips Petroleum Co.), and FBD – 4 (Snamprogetti SpA), are at present of industrial importance.

To produce MTBE from *tert*-butanol [5], isobutene must first be obtained by elimination of water from the alcohol before the olefin can be used for ether production.

Methanol (→ Methanol), the second reactant in MTBE synthesis, is produced at a typical purity of > 99.9 % and is used directly for ether synthesis without further purification. Comparison of today's methanol capacities, which amounts to 32×10^6 t/a, and the methanol demand of 26×10^6 t/a [48] would allow an additional increase of MTBE production of ca. 16×10^6 t/a. Some 25 % of the present methanol output is consumed by MTBE.

4. Production

Methyl *tert*-butyl ether can be obtained by the acid-catalyzed addition of methanol to isobutene [6]. Suitable catalysts are solid acids such as bentonites [7], zeolites [8], [49], [50] and – commonly used in industrial world scale MTBE-production units – macroporous acidic ion-exchange resins [9]. The reaction is weakly exothermic with a heat of reaction of − 37.7 kJ/mol.

The kinetics of MTBE formation have been investigated intensively [9], [51], [52]. It has been shown recently, that the observed reaction rates can be described sufficiently both by a kinetic model according to a Langmuir – Hinshelwood mechanism and by an Eley – Rideal (ER) approach [53]. However, the ER-model seems to be the most probable one. The commonly used kinetic model has been developed by Rehfinger et al. [54]. Because of equilibrium limitations only 92 % conversion can be achieved with equimolar amounts of isobutene and methanol at 333 K. An excess of methanol not only increases the conversion of isobutene but also suppresses its dimerization and oligomerization. Dimerization of isobutene is the most important side reaction of MTBE synthesis [55], [56]. At a molar methanol ex-

cess as low as 10 %, the selectivity for MTBE is practically 100 %.

In recent years, in addition to the Snamprogetti [57] and Hüls (now Oxeno) processes [10], [58], [59] processes developed by Arco [11], IFP [60], and CDTECH (ABB Lummus Crest and Chemical Research Licensing) have been established [12].

Other industrial processes have been developed by DEA (formerly Deutsche Texaco) [13], Shell (Netherlands) [14], Phillips Petroleum [60], and Sumitomo [15]. More than 140 MTBE plants with a total installed capacity of ca. 20×10^6 t/a are on stream [44], [46].

Process Description. Most commercially available processes are comparable and consist of a reaction and a refining section.

Reaction Section. All processes have in common the reaction of isobutene with a certain molar excess of methanol on a macroporous acidic ion exchanger at 50 – 90 °C. In the Snamprogetti, Hüls, and Arco processes, the pressure in the reaction section is chosen so that the reactants over the catalyst are entirely in the liquid phase over the catalyst bed, i.e., between 1.0 and 1.5 MPa. This enhances catalyst life time by reducing the polymerization of isobutene at the catalyst's surface and promotes the selectivity for the MTBE formation. For example, only ca. 100 – 200 ppm by weight of isobutene is converted to diisobutene (2.2.4-trimethylpentene-1 and -2) in the "Hüls-MTBE-Process".

Design of the reaction section is largely determined by the heat of reaction, which must be removed. The heat of reaction depends on the isobutene concentration in the feedstock. In the three processes mentioned (Snamprogetti, Hüls, Arco) adiabatic reactors are always employed with a *FCC – C_4 feedstock*. If *raffinate 1* is used as feedstock, Snamprogetti and Oxeno prefer tubular reactors for reasons of process engineering, whereas Arco employs recycle reactors. In the adiabatic reactors employed by IFP (Institute Français du Pétrol) or CDTECH, which also requires a recycle at higher isobutene concentration, an isobutene conversion of approximately 85 % is achieved. The heat of reaction is removed by partial evaporation of the C_4 hydrocarbons in the reactor as the reaction proceeds. This process design, however, gives rise to a certain loss in selectivity for MTBE. A final isobutene conversion of ca. 97 % is achieved by a subsequent *catalytic distillation.*

In most industrial plants, isobutene conversion of 95 – 97 % is sufficient. *Residual butenes* are mainly used for the manufacture of alkylate gasoline, recycled to the cracker, or simply burned. If they are to be utilized for other chemical purposes such as the production of polymer-grade butene-1, the degree of isobutene conversion must be significantly increased. To overcome the conversion limit of 95 to 97 % posed by the chemical equilibrium, a higher excess of methanol in the feed stream can be used. Unfortunately, this excess methanol remains in the MTBE product. It can, nevertheless, be recovered by distillation, e.g., as a methanol-poor minimum boiling azeotrope with MTBE [19]. Not only does this give MTBE with purities > 99.7 % (balance mainly *tert*-butanol produced by a reaction of isobutene with water dissolved in the feedstock), it also results in isobutene conversions of ca. 98 %. In the Oxeno-MTBE process isobutene conversions of > 99.9 % could be achieved in a two-stage process (see Fig. 1). This conversion corresponds to ca. 300 ppm per weight of residual isobutene in the spent C_4 fraction. Usually, if the feedstock is a raffinate 1 stream, the spent C_4 fraction is called raffinate 2.

This high conversion can also be obtained by using highly sulfonated acidic resins in the reaction section followed by an additional catalytic distillation column in the refining section.

Refining Section. Catalytic distillation (CD) or reactive distillation (RD) refers to a process, where both catalytic reaction and distillation are carried out simultaneously in the debutanizer column. From the viewpoint of reaction engineering, this column acts as a two-phase countercurrent flow, fixed-bed catalytic reactor. Usually CD is defined as a process, in which a heterogeneous catalyst is located in a distillation column. A more common term for this operation is RD. This term does not distinguish between a homogeneous or heterogeneous catalyzed reaction in distillation columns.

The most important advantage of using CD for MTBE synthesis lies in the elimination of equilibrium limitation of isobutene conversion as a result of continuous removal of the reaction product MTBE from the reaction mixture.

Figure 1. Two-stage Oxeno-MTBE-Process

Second stage:
d) Secondary adiabatic reactor; e) Second C_4 distillation tower
Methanol recovery:
f) Methanol extraction; g) Methanol tower

The partly reacted mixture from the reaction section – which is usually in chemical equilibrium – enters the CD column below the catalyst packing zone to ensure the separation of the high-boiling component MTBE from the feed stream. The catalyst packing is installed in the upper mid portion of the column with normal distillation sections above and below.

The CD-based MTBE process was first developed by CR & L using a patented catalyst support system (commercialized as CD MTBE or CD ETHEROL) [16], [61]. The catalyst used in the CD columns is essentially the same as that employed in the reaction section. It is an acidic ion-exchange resin, which is supported by a fiberglass cloth reinforced with stainless steel wire mesh. These fiberglass cloths are rolled to catalyst bales and stacked on sieve trays in the column.

A CD-process has been developed also by UOP and Hüls in 1992, utilizing Koch Engineering's KataMax-technology [62] (commercialized as ETHERMAX process). In this kind of process technology the catalytic section of the CD-column uses a conventionally structured, wire-cloth distillation packing, which contain pellets of strong acidic ion-exchange resin [63]. The benefit in using this type of packing is a very good distribution of liquid and vapor phase at a low pressure drop, an efficient contact of reactants with catalyst pellets, and instantaneous distillative removal of reactants. Therefore, the packing exhibits excellent separation performance combined with an efficient mass and heat transfer for chemical reaction. An analogous catalytic packing system have been developed by Sulzer (commercialized as KataPak) [64] and Montz (commercialized as MultiPak) [65].

CD-technology has the important advantage over conventional unit design (reaction section followed by debutanizing in a distillation column) of lower capital investment costs, if a very high conversion of isobutene has to be achieved. Because in the CD-process both chemical reaction and distillation are carried out in the same

device, at least one process step is eliminated. Beyond this, the exothermic heat of reaction can be used to vaporize the reaction mixture. Therefore, the maximum temperature in the reaction zone is limited to the boiling point of the mixture, so that an efficient and secure temperature control is possible.

One evident disadvantage of the CD-process technology is the fact, that since the debutanizer column must be taken out of operation during exchange of the catalytic packing, also the whole MTBE unit must be shut down. In contrast, in the conventional design, where the reaction section usually consists of two or more fixed bed reactors (e.g., in the two stage Hüls-MTBE-Process), a continued production can be performed at a lower feed rate, while the catalyst is exchanged. In the CD-technology it must also be ensured that a small excess of methanol exists along the reaction zone. In the absence of methanol the exothermic dimerization of butenes take place at high reaction rates. The ensuing sharp temperature rise ("hot spot") will cause irreversible catalyst deactivation and catalyst damage.

Nevertheless, since the mid-1980s most of the MTBE plants, which have been built, were equipped with a CD-column.

In the removal of nonconverted C_4 hydrocarbons from MTBE by distillation, excess *methanol* appears in the distillate, because of formation of an methanol-C_4 azeotrope. The methanol content in the azeotrope depends on pressure and C_4-composition, e.g., at 0.6 MPa the azeotrope contains ca. 2 to 4 wt % methanol. This methanol can completely be removed from the C_4-stream in an extraction column using a countercurrent water wash. The methanol can be recovered by distillation and is recycled to the reaction section.

If methanol losses of ca. 200 ppm by weight are acceptable, methanol recovery from the distillate with molecular sieves is also appropriate [17]. This 200 ppm residual methanol together with dimethyl ether, also formed in trace amounts, can be separated from the butene fraction in a subsequent molecular sieve adsorption unit [18].

Construction Materials. Because corrosive media are not used anywhere and do not result from catalyst disintegration, the entire plant is fabricated from standard carbon steel. Moreover under normal operating conditions, residues, process wastewater, and gaseous emissions are not formed.

Investment costs (inside battery limits, IBL) for a 200 000 t/a MTBE plant (Oxeno-MTBE-Process) in the Federal Republic of Germany, running on raffinate I feedstock, amount to 14×10^6 DM.

5. Environmental Protection

The small amounts of byproducts (see Chap. 6) in MTBE need not be removed if the product is to be used for gasoline. The catalyst is regenerable, and no environmental problems arise from its disposal.

Because MTBE is soluble in water, suitable precautions against groundwater contamination must be taken in loading and storage areas. Recently published complains about groundwater contamination and the reactions taken by public authorities in parts of the United States arose from careless storage of the product. For the environmental significance of MTBE, see Section 11. For emission control in the storage and handling of MTBE, see Chapter 8.

6. Quality Specifications

The usual purity of commercial MTBE is 98 – 99 wt %. The byproducts, *tert*-butanol and diisobutenes, as well as excess, residual methanol, do not have a detrimental effect on octane number improvement through the use of MTBE. Depending on the quality of the C_4 feedstock mixture, the MTBE product may also contain C_5 and C_6 hydrocarbons. A removal of these components by distillation is not necessary in most cases.

A typical MTBE composition adopted worldwide for use in the fuel sector is given below:

MTBE	98 – 99 wt %
Alcohols (methanol, *tert*-butanol)	0.5 – 1.5 wt %
Hydrocarbons (C_5, C_6-hydrocarbons, diisobutenes)	0.1 – 1.0 wt %
Water	50 – 1500 ppm by weight
Total sulfur	max. 10 ppm by weight
Residue on evaporation	max. 10 ppm by weight

For special applications (see Section 10.2), a high-purity MTBE (ether content > 99.98 % wt)

is marketed under the trade name Driveron S by Oxeno. High purity MTBE is also available from Shell and ARCO.

7. Chemical Analysis

Pure MTBE is analyzed by gas chromatography, preferably in capillary columns with a highly polar stationary phase, e.g., TCEP [1,2,3-tris-(2-cyanoethoxy)propane], Carbowax 20 M, or DX-1. For GC analysis of MTBE-containing fuels, an oxygen-specific detector (O-FID) [20] or a column combination technique [21], [22] can be employed. For other references on analysis of MTBE, see [23], [24], [25].

8. Storage and Transportation

Being noncorrosive, MTBE can be handled in the same way as fuel, and the existing distribution system can also be used for fuels containing MTBE. The ether has an indefinite storage life even in the presence of air. Because water is miscible with MTBE (though only slightly), dry storage is required. The product can be stored in nonpressurized containers. Carbon steel can be used as container material, as well as aluminum, brass, copper, polyethylene, or polypropylene. Teflon, Buna-N, and other fuel-resistant plastics and rubbers can be used for seals; the use of vinylidene fluoride-hexafluoropropene copolymer (Viton) is not recommended.

Methyl *tert*-butyl ether has a vapor pressure of 61 kPa at 40 °C. Emission from storage facilities can be controlled or prevented by ordinary measures. The usual safety precautions for highly inflammable liquids must be employed.

Extinguishing agents for fire fighting are powder, carbon dioxide, and alcohol-resistant foam such as Tutogen L (→ Fire Extinguishing Agents, Chap. 3.2.). With alcohol-resistant foams, a higher application rate is necessary for MTBE than for pure hydrocarbons.

Transport classifications are as follows:

ADR/RID II	class 3, no. 3 b; Name of substance: 33/2398 Methyl-*tert*-butylether
ADNR II	class 3, no. 3 b
GGVSee/IMDG	class 3.1
UN no.	2398
ICAO Code/IATA-DGR II	class 3
UN no.	2398

9. Legal Aspects

The principal reason for the current importance of MTBE is environmental legislation (especially in the United States, Japan, and Western Europe). Although laws do not require the use of MTBE, it is often the best way to satisfy their provisions.

In the *European Community*, the Council Directive 85/536/EEC, December 5, 1985 [26], does not require special labeling at filling stations for fuels containing up to 15 vol % MTBE.

In the *United States*, the use of oxygenates in gasoline is governed by EPA waivers from the Clear Air Act. Sun Refining received a provisional waiver in 1988, permitting the use of up to 15 vol % MTBE (2.7 wt % oxygen) [27].

Legislation has developed since oxygenates in fuel have become generally recognized. To reduce carbon monoxide emission and comply with provisions of the Clean Air Act, some U.S. cities and states mandate the use of ca. 2.7 wt % oxygen in fuel (mainly as MTBE) in winter months.

10. Uses

10.1. As an Octane Enhancer

(→ Automotive Fuels)

More than 95 % of MTBE produced are used in the gasoline pool. In the 1980s – 1990s huge production capacities have been erected in order to cover the demand of MTBE. This process has been driven especially by the CAA regulation in the United States. In addition to many other favorable characteristics, the current importance of MTBE is based primarily on its exceptionally good octane-enhancing properties when used as a gasoline blendstock [28], [31]. These antiknock properties are especially important because the use of cheap but toxic alkyllead compounds has been restricted or banned by law, both on environmental grounds and to permit the use of exhaust catalytic converters. Depending on the composition of the base gasoline, blend octane numbers of 115 – 125 (research octane

number, RON) and 92 – 120 (motor octane number, MON) can be achieved. The highest blend values are obtained with saturated, paraffin-rich gasolines; the lowest, with olefin-rich gasolines. The lead and aromatics content also influences the blend octane numbers of MTBE. Because of the relatively low boiling point of MTBE, the effect on the front-end octane number (FON or R-100 °C-ON, i.e., the research octane number of the fraction with a boiling range < 100 °C) is especially pronounced (see Fig. 2) [29].

Figure 2. Ranges of octane improvement by addition of MTBE to an unleaded gasoline with RON = 88, MON = 81, and R-100 °C-ON = 77

Besides increasing the octane number, addition of MTBE to fuel has other positive effects. It does not necessitate any modifications to existing vehicles. The fuel vapor pressure (Reid vapor pressure, RVP) is decreased, so that vapor emissions during automobile fueling and operation are reduced. Addition of MTBE cuts down exhaust emissions, particularly carbon monoxide, unburned hydrocarbons, polycyclic aromatics, and particulate carbon. Although MTBE has a somewhat lower heat of combustion than gasoline, addition of up to 20 vol % neither impairs motor power nor increases fuel consumption. Easier cold starting and prevention of carburetor icing are other advantages. With regard to the hot-weather drivability of modern automobiles, no difference exists between fuels containing MTBE and those without it [30]. Because of the miscibility of water with MTBE, the fuel's cloud point is significantly lowered. The MTBE-blended fuels are compatible with all materials used in automobile manufacture (e.g., gaskets; lacquers; metals in the carburetor, injection pump, or elsewhere; and elastomers).

10.2. Other Uses

Methyl *tert*-butyl ether is also used in the petrochemical industry. Production of isobutene by splitting MTBE is the only application that has been used on an industrial scale (for applications of isobutene, → Butenes, Chap. 9.).

By reversal of its formation reaction, MTBE can be cracked to isobutene and methanol on acidic catalysts at > 100 °C [32]. The methanol obtained as a coproduct is recycled to MTBE synthesis. For economic and ecological reasons, the MTBE-cracking route and that involving the splitting of *tert*-butanol obtained by direct hydration of isobutene [33] will continue to displace the conventional sulfuric acid extraction process for the isolation (recovery) of pure isobutene from C_4 streams [34]. At present, isobutene production with MTBE as feedstock is employed by Exxon Chemical and Sumitomo.

Methyl *tert*-butyl ether itself can be used in a number of chemical reactions, for example, the production of methacrolein and methycrylic acid [35] and of isoprene [36]. For other possible applications, see [37–42] .

The lack of acidic hydrogen atoms makes MTBE a suitable *solvent* for chemical reactions such as Grignard reactions. The preferred grade for this purpose is high-purity MTBE with a residual alcohol content < 500 ppm by weight, such as the product marketed by Oxeno under the trade name Driveron S. Because of its negligible tendency to form peroxides, high ignition temperature, and narrow explosion limits, MTBE is a good solvent for analytical use [42]. It is also used as an *extractant*, for example, in solvent dewaxing of hydrocarbon oils [42], [43].

11. Toxicology and Occupational Health

11.1. Toxicological Profile

As regards its widespread application and the amounts used, MTBE ranges within the top 2 % of all tested chemical substances. According to all of the toxicity data reviewed, in respect of European Union regulations MTBE has been classified as a skin irritant.

Acute Toxicity. Tests with different animal species on oral, dermal, and inhalation application routes indicate a low acute toxicity for MTBE (oral LD_{50} well above 2000 mg per kilogram bodyweight, dermal $LD_{50} > 10\,000$ mg per kilogram bodyweight, inhalation LC_{50} values in the range from 85 – 142 mg/L for 4 h). At high concentrations anesthesia is the most immediate effect (CNS depression). At nonlethal concentrations local irritations, typical for organic solvents, have been observed besides transient behavioral effects.

MTBE was found to be only slightly irritant to the rabbit eye but causes reversible moderate to severe skin effects in rabbits. Animal studies showed no sensitizing potential for neat MTBE.

Chronic Toxicity. The main effects observed in repeated dose toxicity studies via the oral and inhalation routes were CNS depression, irritation of the respiratory and gastrointestinal tract and enlargement of the liver. For the oral route the no observed adverse effect level (NOAEL) in a 90 day test is 300 mg/kg bodyweight per day while it is 800 mL/m^3 or 2880 mg/m^3 in 90 days inhalation tests.

Genotoxicity, Mutagenicity, Carcinogenicity. Neither the structure of MTBE nor the comprehensive number of available in vitro and in vivo mutagenicity tests with MTBE and its metabolite *tert*-butanol provide any indication of possible genotoxic or mutagenic effects. The other metabolite, formaldehyde, has a proven potential of DNA damage, but will be rapidly detoxified when formed in the body. Therefore available test data strongly suggest that with regard to MTBE itself and its metabolites no genotoxic activity should be assumed by MTBE exposure. The absence of genotoxic potential is important when discussing possible carcinogenic effects. MTBE produces tumors in rats and mice at high concentrations. No observed adverse effect concentrations (NOAEC) of 400 mL/m^3 by inhalation and 250 mg/kg bodyweight at oral dose are derived from the tests results. The tumors found have been formed via nongenotoxic mechanisms, and are most probably not relevant to humans. Based on the available data several independent bodies, such as the International Association of Research on Cancer (IARC, WHO-agency), the European Union Working Group on Classification and Labelling of Dangerous Substances, and other bodies recently have not come to the conclusion that MTBE is a human carcinogen. Based on the available data MTBE is not classifiable with respect to its carcinogenic potential for humans.

Reproductive Toxicity. Tests on reproductive toxicity and developmental development shows that MTBE is not significantly toxic to reproduction nor to fetal development.

11.2. Human Experience

As the odor threshold of MTBE in air (0.053 mL/m^3 = 0.19 mg/m^3) as well as odor and taste thresholds in water (15 µg/L and 40 µg/L, respectively) are very low, at low exposure levels effects on humans may be transient and subjectively caused by taste and odor. At 180 mg/m^3 no objective symptoms on the CNS and no signs of irritation of the respiratory tract were reported. Although it is not reported, repeated exposure on skin may result in de-fatting of the skin.

As indicated by all reported human experiences there is no evidence of any adverse effect caused by low exposure levels.

11.3. Health Risk Characterization, Occupational Health

Since the exposure concentrations for workers involved in production of MTBE, blending, distribution and handling of gasoline containing MTBE, service-station attendants and garage workers, and also for consumers filling

MTBE containing gasoline in cars are significantly lower than the no effect levels in toxicity tests, MTBE production and use indicates no concern for human health.

However, compliance by workers with the short- and long-term occupational exposure limits and protection against skin contact is necessary to be protective against the described effects of MTBE. The lowest recommended occupational exposure limits are 270 mg/m^3 (75 mL/m^3) as the short-term and 90 mg/m^3 (25 mL/m^3) as the long-term value.

12. Ecotoxicology

12.1. Ecotoxicity Data

The result of a large amount of acute aquatic toxicity test data available for organisms at different trophic levels indicates low toxicity to aquatic organisms. All measured EC_{50} and LC_{50} values for microorganisms, algae, invertebrates and fish are well above 100 mg/L. Because of the fact that the measured concentrations of MTBE in the environment are significantly lower than the no effect levels in the mentioned tests and the calculated no effect levels for sediment organisms and terrestrial organisms like earth worms, it is verified that the risk for environmental organisms is low.

12.2. Behavior in the Environment

A calculation with McKay level 1 partitioning model estimates that in case of a spillage most of the MTBE (95 %) will distribute in the atmosphere. There MTBE is readily degraded by photochemically produced hydroxyl radicals. The half-life for photodegradation in the air is about 3 – 7 days.

Aerobic and anaerobic degradation in water and groundwater depends strongly on the conditions. With inoculum of predominantly domestic sewage nearly no biodegradation occurs within 28 days in water in a standard test. However, with adapted bacteria MTBE is readily biodegradable under aerobic conditions.

As MTBE is relatively easily soluble in water (about 50 g/L) and will not adsorb on soil, it is easily washed into the groundwater. Biodegradation in contaminated soil and groundwater (remediation) is discussed in Chapter 13.

Due to its physical-chemical properties and metabolism in organisms MTBE is not expected to bioaccumulate and this has been shown to be correct by a bioaccumulation test.

13. Removal of MTBE from Impacted Groundwater

As a component of gasoline, MTBE can enter subsurface environments through a number of release scenarios including leaking underground fuel tanks (LUFT), dispensing equipment, accidental spills during tank refills, leaking fuel pipelines, minor on-going spill incidents, and larger volume surface spills. In many cases, gasoline retail stations and production terminals are sources of MTBE in groundwater. The concentration of MTBE in groundwater and the extent of groundwater contamination depend largely on the volume and duration of a gasoline release and whether remediation has been initiated at the site. As with any remedial effort for most contaminants, source removal is critical for the success of remediation systems at MTBE-impacted sites. A quick response following an accidental release of an MTBE-blended gasoline is of great importance regardless of the selected remediation method since it decreases the size of the area requiring characterization and the volume of groundwater needing treatment thereby minimizing site characterization and remediation costs.

13.1. Overview of MTBE Remediation Technologies

The selection of a remedial strategy at an MTBE-impacted site depends on the volume of contaminated soil and groundwater, contaminant concentrations and mass, site-specific hydrogeological characteristics, and risk-based or regulatory-driven cleanup objectives. Of particular interest at MTBE-impacted sites is the behavior of MTBE relative to other gasoline components in subsurface environments.

The properties of MTBE greatly influence its fate in the environment, govern transport

mechanisms, phase partitioning and biological interactions, and impact the success of remedial technologies. Key physiochemical properties of MTBE were presented in Tables 2 and 3. As compared with toluene, a common gasoline component and groundwater contaminant (→ Toluene, Chap. 2.1.), MTBE has a lower density and boiling point, but a higher vapor pressure and much higher water solubility. The properties of MTBE suggest the following regarding its fate in subsurface environments: (1) MTBE does not readily sorb to soil particles in aquifers; (2) MTBE volatilizes readily from non-aqueous phase liquid (NAPL) sources; and (3) MTBE strongly partitions into the aqueous phase and preferentially remains in water. As a consequence, MTBE can be highly mobile in subsurface environments relative to other gasoline constituents.

Contarary to early reports, most of the technologies used historically at gasoline-contaminated sites are effective at removing MTBE from groundwater.

Successful technologies include groundwater extraction followed by air stripping, advanced oxidation or granular activated carbon systems. In-situ technology options include air sparging, multi-phase extraction, soil vapor extraction, bioremediation and phytoremediation. In addition to single technologies traditionally used at gasoline-contaminated sites, emerging technologies, modifications to existing technologies or the use of a treatment train involving more than one technology can greatly improve MTBE removal efficiency and/or reduce life cycle remediation costs.

13.2. Phase Transfer Technologies

Phase transfer technologies move MTBE from the water phase to either the gas phase (e.g., air stripping) or the solid phase (e.g., granular activated carbon) without chemically transforming it. Consequently, additional treatment steps to destroy MTBE (e.g., off-gas treatment from air strippers) or waste disposal (e.g., spent granular activated carbon) may be required.

13.2.1. Ex-Situ Phase Transfer Technologies

13.2.1.1. Air Stripping

Air stripping is a physical process for removing volatile organic compounds from water. In general, the effectiveness of air stripping increases with a compound's Henry's constant and the operating air-to-water ratio. MTBE's Henry's constant is much lower than that of common groundwater contaminants such as toluene (0.018 – 0.026 vs. 0.27, [66]). Thus, high air-to-water ratios (100 to 250) are needed to remove MTBE from water. Air stripping has been used to successfully remove MTBE at concentrations that are typically associated with groundwater contamination from LUFTs [67]. Evaluation of MTBE performance data from eight case studies of low profile and packed tower air strippers showed that air stripping has the potential to be more widely used in both drinking water and remediation applications [68]. For each of the studies evaluated, MTBE removal efficiencies exceeded 90 %. Because state and/or local air quality regulations sometimes required stripper off-gas treatment (granular activated carbon, thermal and catalytic oxidation, advanced oxidation), process costs can increase significantly.

13.2.1.2. Granular Activated Carbon (GAC)

Although MTBE has a low affinity for sorption to solids, several types of activated carbon including coconut shell or coal-based GAC can be used to remove low concentrations of MTBE in water (200 µg/L) cost-effectively [67], [69]. GAC can be used to treat low flows of water from private wells with low MTBE concentrations. For treatment of higher concentrations of MTBE, GAC can be used as a polishing step in a treatment train following air stripping or chemical oxidation [69]. Background water quality and co-contaminant concentrations influence MTBE removal efficiencies. High concentrations of natural organic matter (NOM) and other gasoline constituents in influent water streams compete with MTBE for GAC sorption sites thereby increasing GAC usage rates and process costs.

13.2.1.3. Other Ex-Situ Phase Transfer Technologies

Results from laboratory and pilot scale studies suggest that synthetic resins have the potential for successful remediation of MTBE-impacted sites [67]. One of the advantages of using synthetic resins is the ease of regeneration relative to GAC. One of the limitations of resins is the experimentally observed reduction in MTBE sorption due to the presence of other gasoline constituents, such as benzene, toluene, ethylbenzene, and xylene (BTEX) compounds and *tert*-butanol (TBA, *tert*-butylalcohol), in contaminated water. This is analogous to the effects of NOM and BTEX on GAC sorption as discussed above. The use of synthetic resins is costly relative to GAC but resins can be designed to achieve a higher degree of selectivity and trend to have a longer lifetime than GAC.

In addition to synthetic resins, other sorbents such as high silica zeolites have been shown to be effective in removing MTBE from contaminated water [70].

Other technologies, such as membranes and solvent extraction, can be used to remove MTBE from contaminated groundwater [71], [72], [73] but only a few bench- and pilot-scale studies have been conducted.

13.2.2. In-Situ Phase Transfer Technologies

Demonstrated in-situ phase transfer technologies include soil vapor extraction (SVE), multiphase extraction (MPE), in-situ air sparging (IAS) and phytroremediation. Emerging phase transfer technologies include steam injection/vacuum extraction and six-phase heating.

13.2.2.1. Soil Vapor Extraction (SVE) and Multi-Phase Extraction (MPE)

Soil vapor extraction (SVE) is commonly used for the remediation of vadose zones at gasoline-contaminated sites. In order to remove MTBE from both saturated and unsaturated zones, other remediation technologies can be used in combination with SVE. The success of SVE has been documented at MTBE-impacted sites when implemented either as the sole technology or in conjunction with other groundwater treatment technologies [74–76]. The combination of SVE and groundwater extraction, known as multiphase extraction, is effective in removing MTBE from contaminated aquifers [75] and is routinely used at many sites. Effectiveness with MTBE can be enhanced if the remediation system is operated under high vacuum.

13.2.2.2. In-Situ Air Sparging (IAS)

In-situ air sparging involves the injection of air below the groundwater table to transfer contaminants from the aqueous phase into the gaseous phase. The injection of air has the additional advantage of introducing oxygen to subsurface environments thereby potentially enhancing aerobic contaminant biodegradation rates. Laboratory air sparging column studies in different soils showed that the rate of MTBE volatilization is very rapid in sandy soils [77]. Results from another laboratory study showed that 85 % of MTBE in water equilibrated with gasoline was successfully removed using air sparging [78]. MTBE recovery rates were shown to increase with increased air injection rates and water saturation levels. Results from a number of field studies revealed that MTBE groundwater concentrations at gasoline-contaminated sites were reduced by 88 to 99 % after two years of air sparging [79]. As a general rule, if the site hydrogeology is conducive to successful use of IAS, e.g., soil porosity is satisfactory, this technology could be very successful at removing MTBE from groundwater.

13.2.2.3. Phytoremediation

Phytoremediation involves the use of plants or trees to either remove or degrade groundwater contaminants. Phytoremediation occurs by plant uptake of the contaminants followed by translocation and accumulation into plant tissues, or transpiration through leaves. In some cases, the breakdown of contaminants can take place either within plant tissues or in the rhizosphere [80]. Phytoremediation is most effective for contaminants with log K_{ow} values in the range of 0.5 to 3.0 [81]. Since MTBE has a log K_{ow} of 1.2, phytoremediation is expected to

be an effective technology at MTBE-impacted sites. Several plant and tree species have been recently reported to uptake MTBE including alfalfa plants [82], poplar trees [80], [83], [84] and Eucalyptus trees [84], [85]. In laboratory studies, poplar trees were shown to remove 30 % of the MTBE in test solutions at concentrations of 300 to 1600 µg/L in a week [81]. Results of several laboratory studies suggest that phytoremediation has the potential to be effective for the removal of MTBE from groundwater, especially at sites where the contaminated groundwater is shallow.

13.3. Transformation or Destruction Technologies

The underlying principle of transformation or destruction technologies is the transformation of MTBE in water to another chemical form either partially (e.g., acetone) or completely (carbon dioxide). Transformation or destruction technologies can either be implemented ex-situ following groundwater extraction (e.g., chemical oxidation, biological treatment) or in-situ (e.g., in-situ chemical oxidation, in-situ bioremediation).

13.3.1. Ex-Situ Transformation Technologies

13.3.1.1. Advanced Oxidation Processes (AOPs) (→ Water, Chap. 10.3.4.)

Advanced oxidation processes involve the use of ozone-peroxide, ozone – UV, peroxide – UV, Fenton's reaction (hydrogen peroxide in combination with iron(II)salts), high-energy electron beam irradiation (E-beam) or sonication-hydrodynamic cavitation. Most of these processes are characterized by the production of hydroxyl radicals. AOP technologies have been tested for MTBE destruction in both laboratory and pilot-scale studies. In addition, some full-scale applications have been reported [86–91]. Common problematic byproducts include bromate due to the reaction of ozone with bromide, and TBA, *tert*-butyl ether (TBE), acetone and formaldehyde from the use of UV – H_2O_2 [91]. Some of these compounds are either more toxic than MTBE or more resistant to oxidation [87], [88].

AOPs are believed to be most efficient for groundwater with MTBE concentrations ranging between 0.1 and 80 mg/L [87]. Although the use of AOPs is effective at treating high concentrations of MTBE, AOP systems can be expensive and can lead to the formation and accumulation of toxic or undesirable byproducts. More research to evaluate the cost-effectiveness and performance of AOPs at field-scale levels is needed.

13.3.1.2. Biological Treatment

Alkyl ethers, such as MTBE, are relatively difficult to degrade because of the high energy required by microorganisms to cleave the ether bond and the resistance of the branched carbon structure to microbial attack [92]. Several early studies reported that MTBE is biologically recalcitrant under most environmental conditions [93–95]. Recent laboratory and field studies, however, have shown that a number of bacterial and fungal cultures from various environmental sources are capable of degrading MTBE under aerobic [96], [97] and anaerobic [98–102] conditions. Microorganisms can either utilize MTBE as a sole source of carbon and energy, or can degrade it cometabolically following growth on short-chain alkanes such as propane.

The biodegradation of MTBE has been demonstrated using both suspended growth and fixed film bioreactors [103–109]. In a growth bioreactor microorganisms were able to reduce MTBE concentrations from 2400 mg/L to 1.6 mg/L with an average removal rate of 96.2 % over the course of the study.

Several types of ex-situ reactors can be used for MTBE treatment including fluidized bed, porous pot, membrane and trickling filter bioreactors. Membrane bioreactors sustain high densities of microorganisms and are therefore suited for treating high strength waste streams as well as waste streams containing slowly biodegraded compounds such as MTBE. In one study, the use of a membrane bioreactor reduced MTBE from high (2000 mg/L) to very low (40 g/L) concentrations during normal operation [108]. The potential for success of ex-situ bioreactors has increased over the last several years with the

isolation of pure cultures capable of degrading MTBE and TBA at relatively rapid rates [96]. For example, two pure cultures designates PM1 and ENV735 are being used commercially in fluidized bed reactors (FBRs). Such systems show great promise for biologically treating MTBE contaminated water streams.

13.3.2. In-Situ Transformation Technologies

13.3.2.1. In-Situ Chemical Oxidation

In-situ chemical oxidation (ISCO) is based on the same principles of advanced oxidation. Most ISCO technologies involve the injection of oxidants into groundwater to produce hydroxyl radicals. Common oxidants include peroxide, permanganate, ozone, and Fenton's reagent. In a successful field scale demonstration, hydrogen peroxide was injected at a site in New Jersey. MTBE concentrations dropped from 6000 µg/L to below detection limits in less than a year [111]. Injection of Fenton's reagent into groundwater at a site in Texas reduced MTBE concentrations by 83.4 % [112]. One of the advantages of ISCO is the potential to destroy MTBE in a relatively short time frame. Technology limitations include effective oxidant delivery and the potential of byproduct formation.

In addition to the injection of ozone as an oxidant, technologies involving ozone sparging are currently being tested. Fine bubbles with a high surface-to-volume ratio are injected into the saturated zone to extract dissolved MTBE from contaminated groundwater. Ozone contained within the bubble and thin film around the bubble is expected to react rapidly and destroy MTBE in the gas phase.

13.3.2.2. In-Situ Bioremediation (see also → Bioremediation)

In-situ bioremediation involves the use of indigenous or exogenous microorganisms to either destroy or immobilize contaminants. In-situ bioremediation strategies could involve direct metabolism, cometabolism, bioaugmentation or some combination thereof. Results from pilot studies showed that bioremediation approaches involving oxygen injection and/or bioaugmentation have a strong potential for success at MTBE-impacted sites [110], [113]. In addition, a recent study has demonstrated the success of propane injection and bioaugmentation at an operating service station in New Jersey where a 93 % reduction in MTBE concentration was achieved within two months of system operation [108].

Fortum Oil and Gas Oy and Oxeno Olefinchemie GmbH, two member companies of EFOA (The European Fuel Oxygenates Association – www.efoa.org) have been contributing to the Chapters 11, 12, and 13.

1. Introduction

Mica consists of a group or family of closely related silica-based minerals which share a number of characteristic physical, chemical, and optical properties. It has had mystical associations for millenia. In classical Hindu writings from 2000 B.C., mica was regarded as petrified lightning flashes and was believed to possess potent medicinal powers. It was known as Abrak and Abhra, Hindu words for clouds and heaven. The actual name mica is thought to be derived from the Latin "micare", meaning to shine or glitter, a term used by AGRICOLA in 1546.

2. Structure and Properties

Structure. Micas are members of a class of silicates known as phyllo- or sheet silicates (→ Silicates), a term which reflects their crystal structure. The general chemical formula for mica is $W(X,Y)_{2-3}Z_4O_{10}(OH,F)_2$, where W corresponds to K, Na, and Ca, or more rarely Ba, Rb, and Cs. The X, Y site is occupied by any two ions of Al, Mg, Fe, or Li, and less frequently of Mn, Cr, and Ti. Normally Z is Si or Al, but may also be Fe or Ti. As with other silicates the primary building unit of mica is the SiO_4 tetrahedron. The tetrahedra are linked together via their three basal oxygen ions to form a network of hexagonal cells with the apical oxygen ions all pointing in the same direction (Fig. 1). The idealized basic structural unit of mica comprises two layers of tetrahedra in which the apical oxygen ions point toward each other. The voids between the bases of tetrahedra in adjacent layers and between adjacent apical oxygen ions provide the cation sites (Figs. 2 and 3). The interapical plane is occupied by the octahedrally coordinated X, Y ions which may be any two of Al, Mg, Fe, or Li. The W sites (filled by K, Na, and less frequently Ca cations) are in 12-fold coordination with the basal oxygen ions. Most commonly these stacking sequences lead to either one- or two-layered monoclinic cells (denoted as 1 M and 2 M_1), an alternative two-layered monoclinic cell (2 M_2), or a three-layered trigonal unit (3 T).

Micas can be subdivided into di-octahedral and tri-octahedral classes where the number of X and Y ions is 4 and 6, respectively.

The various types of mica are summarized in Table 1. The most commonly occurring forms are *muscovite* (potassium – aluminum) and *phlogopite* (magnesium – iron). Biotite and phlogopite are members of a continuous structural and chemical series. Differentiation between them is somewhat arbitrary; some authorities use the Mg : Fe ratio as a criterion, phlogopite having an Mg : Fe ratio $> 2:1$ and biotite a ratio $< 2:1$ [1], [2].

Table 1. Most important types of mica

Name	CAS registry number	Formula	Unit cell dimensions $a : b : c$, nm	Cell designation
Muscovite	[*99401-63-5*]	$K_2Al_4[Si_6Al_2O_{20}](OH,F)_4$	0.519 : 0.904 : 2.008	$2M_1$
Biotite	[*112593-95-0*]	$K_2(Mg,Fe^{2+})_{6-4}(Fe^{3+},Al,Ti)_{0-2}[Si_{6-5}Al_{2-3}O_{20}](OH,F)_4$	0.53 : 0.92 : 1.02	1M
Phlogopite	[*110710-26-4*]	$K_2(Mg,Fe^{2+})_6[Si_6Al_2O_{20}](OH,F)_4$	0.5314 : 0.9204 : 1.0314	1M
Lepidolite	[*114705-28-1*]	$K_2(Li,Al)_{5-6}[Si_{6-7}Al_{2-1}O_{20}](OH,F)_4$	0.53 : 0.92 : 1.02	1M
			0.92 : 0.53 : 2.00	$2M_2$
		$3K(Li,Al)_{2.5-3.0}[Si_{3-3.5}Al_{1-0.5}O_{10}](OH,F)_2$	0.53 : – : 3.00	3T
Zinnwaldite	[*116813-68-4*]	$K_2(Fe^{2+}_{2-1},Li_{2-3}Al_2)[Si_{6-7}Al_{2-1}O_{20}](OH,F)_4$	0.527 : 0.909 : 1.007	1M
Paragonite	[*106495-33-4*]	$Na_2Al_4[Si_6Al_2O_{20}](OH)_4$	similar to muscovite polymorph	$2M_1$
Glauconite	[*102785-61-5*]	$(K,Na,Ca)_{1.2-2.0}(Fe^{3+},Al,Fe^{2+},Mg)_{4.0}[Si_{7-7.6}Al_{1-0.4}O_{20}](OH)_4 \cdot n\,(H_2O)$	similar to biotite 1M polymorph	
Margarite	[*1318-86-1*]	$Ca_2Al_4[Si_4Al_4O_{20}](OH)_4$	0.513 : 0.892 : 1.950	$2M_1$
Clintonite, xanthophyllite	[*12199-34-7*]	$Ca_2(Mg,Fe)_{4.6}Al_{1.4}[Si_{2.5}Al_{5.5}O_{20}](OH)_4$		$2M_1$
				1M

The less common micas include the lithia-rich varieties, *lepidolite* and *zinnwaldite* (→ Lithium→ Lithium), as well as the sodic variants, *paragonite* and *glauconite*. Substitution of Ca for K and Na in the W sites produces the so-called brittle micas– *margarite*, *clintonite,* and *xanthophyllite*.

The presence of cations such as Mg, Fe, Al, and Li in the crystal lattice introduces a stagger which manifests itself in the monoclinic symmetry of the mineral. A feature also shared by most micas is their water content which occurs as hydroxyl ions in the center of the hexagons [4 (O) 2 (OH) planes in Fig. 2 A, see also Fig. 3] and can attain 4 – 5 wt %.

Figure 1. Illustration of a tetrahedral $(Si,Al)_4O_{10}$ layer in mica with apical oxygen atoms pointing upward [2]
Open circles indicate oxygen atoms, filled circles indicate silicon (or aluminum) atoms.

Stains occur in sheet mica and can take the form either of mineral inclusions or discoloration due to the presence of inorganic and organic compounds. These stains are detrimental to the quality of the sheet and may be coincident with, or cut across, the cleavage plane. Examples include those formed during mica crystallization and include mottling, mineral inclusions, and intergrowths. Circulating groundwater may also cause staining.

Properties. Physical properties of muscovite and phlogopite are listed in Table 2. Possibly the most characteristic physical property shared by mica minerals is a perfect basal cleavage which permits them to be split into thin sheets. This is an expression of the layered crystal structure of the mica lattice. A special physical characteristic of mica is its flexibility and elasticity which distinguishes it from minerals such as vermiculite, talc, and chlorite.

Micas are generally resistant to chemical attack with the exception of muscovite (which decomposes in hydrofluoric acid) and phlogopite (which is mildly attacked by hydrochloric acid and decomposes in hot sulfuric acid). Micas can withstand elevated temperatures, muscovite being stable up to 400 – 500 °C, whereas phlogopite decomposes at ca. 850 – 1000 °C. For this reason mica is used as a thermal insulator and optical window in a variety of furnace applications.

In addition to its inertness and thermal resilience, mica also possesses valuable electrical properties including high dielectric strength, uniform dielectric constant, capacitance stability, low power loss, and high electrical resistivity. Hardness typically varies in the range 2 – 3 on the Mohs scale although in brittle micas it can exceed 4.

Muscovite tends to be lighter in color (from colorless to various shades of green – red) than phlogopite and biotite. The color of phlogopite is determined principally by its iron and titanium content. High titanium levels produce a red –brown shade whereas low titanium and high iron impart a green – brown hue. Biotite is generally much darker, often occurring in shades of brown and black.

Figure 3. Three-dimensional structure of mica [2]
In fluoromicas the hydroxyl ions are partially or totally replaced by fluoride ions.

Table 2. Physical properties of mica

Property	Muscovite	Phlogopite
Density, g/cm^3	2.75 – 3.1	2.75 – 3.2
Modulus of elasticity, kN/mm^2	160 – 220	160 – 190
Tensile strength, N/mm^2	250 – 300	250 – 300
Mohs hardness	2.8 – 3.2	2.5 – 2.8
Electric strength, kV/mm for		
0.1 mm thickness	200	150
Volume resistivity, $\Omega \cdot$ cm		
23 °C	$10^{16} - 10^{17}$	10^{14}
500 °C	$10^{8} - 10^{10}$	10^{10}
Relative permittivity at 1 MHz	6 – 8	5 – 6
Dielectric loss at 1 MHz		
23 °C	10^{-4}	10^{-3}
100 °C	10^{-3}	5×10^{-2}

Linear thermal expansion coefficient, 10^{-6} K^{-1}	10	13
Thermal resistance, °C	500	700
Specific heat capacity, J kg^{-1} K^{-1}	850	850

3. Occurrence

Muscovite occurs in various geological environments, including acid igneous rocks such as granites and pegmatites, and also in regionally metamorphosed sediments exemplified by phyllites, schists, and gneisses. It occurs less frequently in sedimentary rocks.

Biotite is the most geologically ubiquitous mica, being the most common mica in acid igneous rocks. It also occurs in gabbros, norites, and diorites and is a characteristic component of calcalkaline rocks. Less frequently it is found in lavas such as rhyolite, trachyte, andesite, and basalt. *Phlogopite* has two principal occurrences, as a component of ultrabasic rocks such as peridotite, and also in metamorphosed limestones.

The lithium micas, *lepidolite* and *zinnwaldite*, are found principally in pegmatites and high-temperature veins. *Glauconite* occurs solely in sedimentary environments.

Only two types of mica are commercially important–muscovite and phlogopite; lepidolite was formerly extracted as a source of lithium (→ Lithium and Lithium Compounds). Two main forms of commercial mica are produced–sheet and ground mica. India is the primary source of sheet mica while the United States is the major producer of ground mica (predominantly muscovite).

North America. In the United States the principal mica-bearing regions are the Blue Ridge and Piedmont provinces of North and South Carolina. North Carolina produces ca. 60 % of the total U.S. output, derived principally from alaskite in the Spruce Pine district which contains 60 % feldspar, 25 % quartz, and 15 % muscovite [3].

Kings Mountain in the Piedmont province of North Carolina hosts a belt of lithium-bearing pegmatite dikes which contain feldspar, quartz, and ca. 60 % muscovite.

Several mica-producing plants exist in South Carolina, one of which supplies sericite (a fine-grained muscovite) from a schist.

In the west of the United States, muscovite is produced in small tonnages from pegmatites and mica schists. In the Picuris range in New Mexico mica is derived from a Precambrian quartz – muscovite schist. The ore typically comprises 38 % muscovite and 60 % quartz [4]. In South Dakota one pegmatite source of by-product mica is currently being exploited. There is also some pegmatite production in the New England region.

In Canada mica production is confined to the large phlogopite deposit at Suzor in Quebec. This medium- to coarse-grained intrusive rock comprises 90 % phlogopite, 8 % pyroxene, and 2 % feldspar. Estimated mica reserves within 50 m of the surface total 27×10^6 t [5].

South America. Brazilian muscovite is derived from a belt of pegmatites some 450 km long running parallel to the Minas Gerais coastline. The pegmatites tend to be zoned, with mica occurring in cavities as well as disseminated throughout the body. They often exhibit preferential weathering and the bodies show considerable variation in form, size, and attitude to the country rocks. The restricted size and remoteness of these bodies severely limit their exploitation [6].

India. India is the world's principal source of sheet mica, accounting for 80 % of global supply. In addition it is an important producer of mica scrap. Bihar is the major producing state, accounting for more than 50 % of output, while Andhra Pradesh produces almost 30 %. The balance comes from Rajasthan, Tamil Nadu, Ker-

ala, and Orissa. Practically all output is muscovite although Kerala produces phlogopite [7].

The mica from the three principal state producers is derived from granitic pegmatites. These bodies vary in attitude from horizontal to subvertical while thickness is in the 1 – 30 m range.

Bihar is the country's principal source of premium-grade sheet muscovite and is renowned for its ruby mica. The production zone is 32 km wide and 145 km long. The mica-bearing pegmatites occur in mica schists and micaceous quartzite.

Rajasthan is the second most important Indian source with production confined to a belt 100 km wide and 320 km long. The rocks are similar to those in Bihar and the pegmatite dikes are steeply dipping bodies, some of which are zoned and possess a complex mineralogy [8].

Most Andhra Pradesh output comes from the Nellore mica district, an arc-shaped zone 100 km long and 15 km wide. Around 70 % of micaceous pegmatites occur in biotite schist and 10 % in hornblende schist [9]. Most output is of green muscovite.

Africa. There are three main sources of mica in Africa–Madagascar, the Republic of South Africa, and Zimbabwe. Tanzania was formerly a source of sheet mica.

Madagascar, along with Canada and Finland, is one of the world's principal sources of phlogopite. The mineral is mined in the southeastern part of the country where it occurs in 0.3 – 2 m thick pegmatite dikes and pockets in association with pyroxenite bodies. Underground mining is carried out in the Berakety and the Ambovombe districts. Nominal amounts of sheet mica are produced [3].

In the Republic of South Africa, muscovite is produced in the Letaba district of eastern Transvaal where the mica occurs in coarse-grained pegmatites. Mica also occurs in the Kenhardt and Namaqualand districts of the Cape Province where it is hosted by complex pegmatites. Mica production from pegmatite source rocks in Zimbabwe is concentrated in a region northwest of Harare.

Europe. In Europe phlogopite is produced as a coproduct of apatite mining at Siilinjarvi in central Finland from a subvertical tabular micaceous carbonatite ore body [10]. Some mica is also produced in Norway as a byproduct of feldspar mining. France (principally Brittany) and Spain produce sizeable quantities of mica as a byproduct of kaolin extraction.

former Soviet Union and China. The former Soviet Union and China are both major mica producers. In the former Soviet Union mica occurs in Karelia (where it is produced as a byproduct of feldspar extraction from zoned pegmatites), the Kola Peninsula, the East Sayan region, and the Kondakovsky region.

4. Processing

Mica can be used in two principal forms–sheet and ground. The former is categorized in terms of sheet purity, sheet thickness, and useable area. Ground mica is processed either dry or wet.

4.1. Sheet Mica

Sheet mica occurs naturally in pegmatites as hexagonal blocks which, owing to the mineral's perfect basal cleavage, are referred to as "books". Its mode of occurrence and the nature of the mineral require sheet mica to be mined and dressed by hand. Upon removal the "book" is cobbed or cleaned by hand to remove adherent quartz or feldspar, and then split with knives into successively thinner sheets. Block, thins, films, and splittings are the four categories of sheet mica classified according to lamina thickness and defined by the Indian Standards Institute, the British Standards, and the American Society for Testing and Materials.

Block mica is knife-dressed sheet mica of which 95 wt % has a minimum thickness of 0.2 mm, with the remainder having a minimum thickness of 0.18 mm. The minimum useable area is 625 mm^2. *Thins* are defined as knife-dressed sheets with a thickness of 0.05 – 0.18 mm. *Films* are split from superior quality block mica; they overlap with thins in that they have thicknesses of 0.02 – 0.18 mm. *Splittings* are laminae with a maximum thickness of 0.03 mm and a minimum useable area of 450 mm^2.

Table 3. Indian areal classification system for mica [11]

Designation		Useable rectangle,	Minimum dimension,
Old ∗	New	cm^2	cm
OOEE Sp.	630	>645.2	10.2
OEE Sp.	500	516.1 – 645.2	10.2
EE Sp.	400	387.1 – 516.1	10.2
E Sp.	315	309.7 – 387.1	10.2
Sp.	250	232.3 – 309.7	8.9
1	160	154.8 – 232.3	7.6
2	100	96.8 – 154.8	5.1
3	63	64.5 – 96.8	5.1
4	40	38.7 – 64.5	3.8
5	20	19.4 – 38.7	2.5
5.5	16	14.5 – 19.4	2.2
6	06	6.4 – 14.5	1.9
7	05	4.8 – 6.4	1.6

∗ O = over; E = extra; Sp. = special.

In addition to classifying sheet mica on the basis of lamina thickness, a grading system also exists for sheet purity and the maximum useable rectangular area that can be cut from a single lamina. Muscovite sheet can be also divided into two color groups–ruby and green. Minor differences exist between the Indian and American classification systems: the Indian system classifies according to 13 grades (Table 3) whereas the American system uses 12. Similarly, on the basis of sheet clarity and freedom from deleterious stains, the Indian system identifies 16 grades (Table 4).

Table 4. Indian visual classification system for mica

Designation	Appearance
V-1	ruby clear
V-2	ruby clear and slightly stained
V-3	ruby fair stained
V-4	ruby good stained
V-5	ruby stained “A”
V-6	ruby AQ
V-7	ruby stained “B”
V-8	ruby BQ
V-9	ruby heavy stained
V-10	ruby densely stained
V-11	black dotted
V-12	black spotted
V-13	black/red stained
V-14	green/brown 1st quality
V-15	green/brown 2nd quality
V-16	green/brown stained or BQ

Small offcuts of sheet mica may be bonded together artificially to form *worked* or *manufactured mica* which is generally classified into three categories [13]:

1) *Micanite or Built-up Mica.* This is produced from thin interleaved splittings arranged in layers and cemented by an artificial binder and compressed at 170 – 180 °C. Typical binders include shellac, epoxy resins, and silicone resins.
2) *Reconstituted Mica or Mica Paper.* This consists of fine flakes (40 – 2000 µm) of high-quality scrap mica pressed into sheets in a continuous film and generally impregnated with a binder.
3) *Glass-Bonded Mica.* This consists of fine particles bonded by borate or borosilicate glass with a low melting point.

4.2. Ground Mica

The raw material used as feedstock for ground mica is mica scrap. Crude mica ore is crushed with jaw and roll crushers. Originally mica scrap was discarded waste from the mining and production of sheet mica but nowadays scrap is predominantly derived from raw material unsuitable for sheet mica. More than 90 % of ground mica output relies on muscovite scrap obtained from pegmatites or as a byproduct from feldspar and kaolin extraction [14]. The origin, type, and quality of the raw material determines its end use.

Dry Ground Mica. Production of dry ground mica in the United States is influenced by its use in plasterboard jointing compounds. In this respect the United States differs from most other countries. Most production utilizes < 3.35 mm (6 mesh) scrap as feedstock which is subjected to air micronization; the oversize fraction > 150 – 250 μm (10 – 60 mesh) is removed on dry screens. Mica used in oil-well drilling is generally a byproduct of feldspar and kaolin extraction, having been segregated by flotation or water classification. The mica is dried and then sieved with multideck screens, the oversize particles (> 8 mm) are subjected to impact milling.

Outside the United States dry ground mica is obtained primarily from premium scrap (> 25 mm) which is introduced into high-speed hammer mills before being "topped" and "tailed" through vibrating screens. These products tend to be highly delaminated and are termed high aspect ratio flakes and powders. Some oil-well grade mica is derived from the production of mica scrap at the mine by "winnowing" the output from the primary crusher through air boxes and cyclones [14].

Wet Ground Mica. In wet grinding high-quality mica scrap is ground with up to 20 wt % water in edge-runner mills. It is then dried and classified to 150, 75, and 45 μm (100, 200, and 325 mesh sizes, respectively). Wet ground mica particles have a typical thickness of 0.1 – 0.8 μm and a high aspect ratio.

Due to the nature of the wet grinding process, the resultant flakes possess smooth edges and tend to be quite flat with good lubricity characteristics. In contrast dry ground mica particles tend to have a poor aspect ratio. The milling process also produces irregular edges which adversely affect lubricity. Consequently wet ground or micronized mica (see below) tends to be used in higher value markets.

Micronized mica is produced by grinding fine-grained byproduct scrap to give a particle size below 40 μm. This is achieved by propelling the particles at high speed into a confined enclosure which results in interparticle comminution. Superheated steam or compressed air can be used as the vehicle to effect micronization, particle size being controlled by residence time in the mill and removal of oversize particles by air classification [14].

5. Uses

5.1. Sheet Mica

The electrical industry has traditionally been the most important market for sheet mica, accounting for over 90 % of output. Within this industry sheet mica enjoys a number of applications by virtue of its thermal and electrical insulating properties, its inertness and resistance to chemical attack, and its translucency (→ Insulation, Electric, Chap. 3.1.1.1.).

Sheet mica possesses several unique electrical properties including high dielectric strength, uniform dielectric constant, capacitance stability, low power loss, and high electrical resistivity. Formerly sheet mica was used in the electrical heating elements of household appliances. Nowadays this market generally uses the cheaper reconstituted micanite product.

Vacuum tubes and capacitors for radios and televisions still incorporate sheet mica, although in color televisions mica has been largely replaced by solid state electronics.

Stacked and silvered mica are used in capacitors. Stacked mica consists of a multilayered "sandwich" of thin mica plates alternating with silver foil. The mica flakes have a typical thickness of 10 – 100 μm. Capacitance is determined by the number of repetitions in the stack and also by the mica thickness, the thinner the mica the higher the capacitance. In silvered mica, silver electrodes are printed and fired onto the mica plates which are then cut to the requisite size and the edges reinforced by silver paste. The plates are then stacked to give the required capacitance. Stacked mica is commonly used in transmitter circuits whereas the silvered variety (available in riveted, clamped, and sintered forms) finds applications in oscillators, filters, transmission circuits, and delay lines. Alternative capacitor materials (ceramics, glass, and plastic) although cheaper than mica, do not possess its range of properties which include dielectric stability at high frequencies up to 500 MHz. A tolerance of ± 1 % can be achieved with mica and mica capacitors exhibit negligible drift. High-grade ruby sheet is favored in capacitor applications

because of its chemical purity. The green variant is not suitable owing to the presence of deleterious elements such as iron which cause current leakage and are consequently intrinsically weak insulators.

The electrical, mechanical, and thermal properties of mica are utilized in the armaments industry. Phlogopite is incorporated in the battery units of heat-seeking missiles. By virtue of its softness and superior thermal insulation characteristics, Madagascar phlogopite is reportedly a favored medium for this application [13]. This mineral is capable of maintaining its thermal integrity at 900 – 1000 °C, giving it a 300 °C advantage over muscovite.

Mica is used for diaphragms in underground breathing apparatus for miners. Tanzanian mica is preferred because of its flatness which permits a good airtight seal. Gauge protectors in high-pressure boilers utilize the translucency, thermal resilience, and mechanical strength of mica. In addition resistance of mica to attack by many hazardous chemicals is a further asset. Superior-grade ruby or green mica is also used for circular compass cards in naval gyro compasses. Green muscovite is also commonly used in optical pyrometers; other optical applications include retardant plates which utilize the birefringent properties of the mineral.

5.2. Ground Mica

Particle sizes of ground mica products used in various applications are listed in Table 5.

Jointing Compounds and Fire Boards. Dry ground mica used in joint cements consisting of gypsum-based plaster imparts crack resistance and promotes smooth finishing. Mica is used at levels of 10 – 12 wt % in such cements to fill the gaps between plasterboard sheets. Its main function is to inhibit the formation of cracks that would allow passage of fire. In gypsum-based plaster cements its platy nature (i.e., occurrence in the form of flat flakes) aids smoothing because the flakes orientate themselves parallel to the substrate; its thermal insulating properties are also beneficial.

Mica is also important in the fire protection industry and is incorporated directly into cementitious fireboards. Mica's main virtues are its lack of shrinkage and its thermal resilience at high temperatures which minimize cracking and help partitions to maintain their structural integrity. For this application the mica should have a low magnesium oxide content, because high levels can cause shrinkage problems.

Plastics. Both muscovite and phlogopite can be incorporated as fillers in plastics (→ Plastics, Additives), phlogopite being chosen where color is unimportant. Dry ground, wet ground, and micronized mica can all be used depending on the type of plastic. Generally the principal properties mica confers on a plastic are:

1) Significant increase in tensile and flexural modulus and decrease in elongation
2) Reduction in thermal expansion and inhibition of nonuniform shrinkage likely to cause warping
3) Increased heat distortion temperature
4) Enhanced impermeability to fluids because of the planar orientation of mica platelets
5) Inertness to UV light, microwaves, and most chemical reagents
6) Improved dielectric properties

A further improvement has been the advent of silane and organosilane compounds for coating both wet and dry micas. Silane coating is thought to facilitate covalent bonding between the mica surface and the surrounding host polymer at elevated temperature and also improves dispersion of the mica within the polymer. Silane-treated wet ground mica is only marginally inferior to glass fibers as a polypropylene reinforcement additive [15].

One major area of utilization is in the automotive industry for "under the hood" applications of plastics such as headlight surrounds, dashboard components, molded rear seat backs, and car trims [16].

Oil-Well Drilling. In this application mica acts as a contingency commodity and its use in drilling is intermittent. It is used in drilling muds to inhibit water loss during drilling. The mica flakes block any cracks or fissures thereby reducing or eliminating loss of drilling fluid. It is used in a variety of grain sizes from coarse (5 – 12 mm) to fine (1.3 – 2 mm). In terms of product specifications this market places the

Table 5. Particle sizes of ground mica products ∗ [12]

Particle size,	Dry ground					Wet ground,	Micronized,
µm	Joint cement	Plastics	Oil-well		Welding rods	rubber grade	paint grade
6400			100				
2800			80	100	100

75	85	35				85	
53	75	20				80	100
44	70	5				75	99.9

∗ Values are expressed as percentage of total particles smaller than the specified size.

lowest demands on mica quality, only low-grade dry ground material is used.

Welding Rods. Dry ground mica is used as a component of rutile electrodes for welding mild and general steels. The mineral prevents cracking, serves as a flux control, and aids the coating of flux onto the electrode.

Rubber. Wet ground mica is also used as a mold release agent in the manufacture of rubber tyres.

Paints. Dry ground, wet ground, and micronized mica are used as fillers in paints. Micronized mica is widely used in emulsions with loading levels in the 10 – 20 % range. It improves the quality of the paint by promoting a matt finish, durability, and resistance to chemical attack and by acting as an anticracking agent. In addition mica helps to control paint flow and enhances scrub resistance and lightfastness. The plate-like mica particles align themselves parallel with the substrate. This not only improves adhesion of the paint to the substrate but also inhibits entry of water thereby improving durability. High aspect ratio wet ground mica is commonly favored for this application because the particles are flatter and, having been ground in an aqueous environment, are less likely to contain soluble salts that can reduce the shelf life of a paint [16]. Due to costs, micronized mica is, however, replacing wet ground mica in paints. Micronized mica is used almost entirely in paint formulations.

Nacreous Pigments. Nacreous (pearlescent) pigments rely upon light transmission, reflectance, and interference to reproduce a "mother of pearl" effect (→ Pigments, Inorganic). Mica is used as a substrate upon which a thin coating of titanium dioxide or other metal oxide is deposited. Both muscovite and phlogopite can be used. Mica is selected by virtue of its relative cheapness, platy morphology, and translucency. Mica particles used in pearl luster pigments are usually 3 – 150 µm in diameter with thicknesses of 200 – 500 nm. Particles below 20 µm produce a satin sheen, those in the 20 – 50 µm range give an optimal pearlescent effect, while those greater than 100 µm produce a sparkling finish. A major area of application is the automotive industry. Printing inks and undercoats for household paints are other markets.

Textured Coatings. Dry ground mica acts as a reinforcing filler in plaster for textured coatings where its main function is to control shrinkage and cracking, and maintain plasticity. The textured plaster coatings are used solely for decorative purposes.

6. Toxicology and Occupational Health

It has yet to be proved if mica dust is hazardous but several authorities have defined limits on permissible dust levels. The ACGIH has adopted threshold values for mica of 6 mg/m^3 for total

dust and 3 mg/m^3 for respirable dust. The Health and Safety Executive of Great Britain specifies a total airborne dust level for all mica grades of 10 mg/m^3 with an additional limit of 1 mg/m^3 for the respirable portion [14].

7. Economic Aspects

World mica output for 1987 totalled approximately 267 000 t of which more than half (147 000 t) was produced by the United States (Table 6). The equivalent figure for 1986 was 134 000 t, of which ground mica sales amounted to 116 000 t (96 000 t dry ground mica and 20 000 t wet ground material). Jointing compounds account for approximately 50 % of the U.S. ground mica market. India's output in 1987 amounted to 10 547 t, accounting for approximately 80 % of global sheet mica production.

Sheet mica has witnessed a gradual, probably terminal erosion of its traditional markets over the last three decades following the advent of solid state electronics. This is in sharp contrast to ground mica where demand for fireboard and jointing compounds is underpinning the market. The greatest potential for future growth in ground mica consumption lies in its expanding use in pearlescent pigments and as a filler in plastics.

8. Fluorinated Micas

In fluorinated micas (fluoromicas) hydroxyl ions in naturally occurring micas (see Fig. 3) are replaced in part or completely by fluorine. Substitution occurs with a minimum of strain as judged by the similarity of the Shannon and Prewitt atomic radii for fluorine (0.1285 nm) and oxygen (0.135 nm; interatomic distance (OH) = 0.097 nm). Fluorinated micas became of importance during World War II because of the limited access to natural micas. The mica of choice was *fluorophlogopite* [*12003-38-2*], $KMg_3AlSi_3O_{10}F_2$, which could be manufactured in sheets up to 7.5×12.5 cm^2 at atmospheric pressure by melting or solid state reaction of the raw materials (potassium fluorosilicate, feldspar, magnesia, alumina, and quartz sand). Care had to be taken that the fluorine levels were sufficiently high (ca. 12 mol %) to prevent the formation of fluoroamphiboles.

Fluorophlogopites have significantly different properties from their hydroxyl counterparts. They are harder, have a higher specific resistivity and dielectric constant, a smaller interlayer distance (0.9978 versus 1.0149 nm), and a higher maximum use temperature (1200 °C versus 400 – 500 °C for muscovite or 850 – 1000 °C for phlogopite). In spite of these improved properties, the industrial uses of fluorophlogopite as a dielectric or insulating material disappeared with the advent of microelectronics. The high use temperature of fluorophlogopite may make it desirable as a pillared clay molecular sieve – use of hydroxyl phlogopite as a cesium-selective ion sieve has been described [16]. Fluorophlogopites are also suited as a coating component for high-quality welding electrodes, which require hydroxyl-free minerals to minimize the concentration of diffusable hydrogen in the weldmetal.

The fluoromica field has been given new impetus with the invention of machinable and castable glass ceramics (→ Glass Ceramics, Chap. 4.3.) and synthetic micas. Two types of glass ceramics have been developed, one based on fluorophlogopite, $KMg_3AlSi_3O_{10}F_2$, with the trade name Macor [17], the other based on tetrasilicic mica, $KMg_2 \cdot 5\,Si_4O_{10}F_2$, with the trade name Dicor [18]. Compositions of these glass ceramics are given in Table 7.

Table 7. Commercial fluoromica glass-ceramic compositions (mol %) ∗

Oxide	Macor	Dicor
SiO_2	42.2	46 – 57
B_2O_3	6.6	
Al_2O_3	8.8	0 – 1
MgO	19.3	22 – 23
K_2O	5.4	8 – 9
F	17.8	13 – 21
ZrO_2		0 – 1
CeO_2		0.02

∗ Macor and Dicor are registered trade names, their composition is:

Macor $K_{1-x}Mg_3Al_{1-x}Si_{3+x}O_{10}F_2$

Dicor $K_{1-x}Mg_{2.5+x} \cdot 2\,Si_4O_{10}F_2$ $x < 0.2$

Macor glass ceramic is manufactured by pouring a fluorine-rich, phase-separated glass into rods, bars, or sheets, ceramming the cast material with a controlled heat cycle to cause for-

mation of the fluorine-based mica crystals in the parent glass, and finishing the material to standard shapes and sizes; no firing is required after machining. Macor is a machinable glass ceramic that consists of ca. 55 vol % crystal and 45 vol % residual glass. The key to its machinability lies in its two-phase microstructure–randomly oriented mica crystals are formed in a glass matrix. Physical properties follow:

Density	2.52 g/cm^3
Porosity	0 %
Knoop hardness	250
Maximum use temperature	1000 °C
Linear thermal expansion coefficient	94×10^{-7} K^{-1}
Compressive strength	340 MPa
Flexural strength	100 MPa
Dielectric strength (a.c.)	1000 mV
Volume resistivity	$> 10^{14}$ Ω · cm

Properties are shown as a function of temperature in Figure 4. Macor has been employed in a wide range of applications such as vacuum-tight hermetic seals, headers and windows for microwave tube parts, retaining rings and hinge points for the space shuttle orbiter, and welding equipment nozzles.

Dicor glass ceramics are used in dental restoration. A potassium magnesium fluorosilicate melt is cast at 1400 °C by the lost wax technique. A centrifugal force generated by spinning pulls the melt tightly into the mold cavity. After removal of the cast, a glass crown is left which upon heat treatment turns into a glass ceramic. The modulus of rupture and compressive strength of this glass ceramic are three times those of conventional dental porcelain. The thermal conductivity and hardness are comparable to those of natural teeth.

Some forms of fluoromica sheet silicates may be processed into gels due to their propensity to hydrate, swell, and disintegrate into small particles in aqueous solutions. Hydration of the octahedral layer causes debonding of the tetrahedral sheets. Such gels can be processed into thin, continuous sheets of mica (e.g., for paper). Suspensions of these thin sheets can be formed into articles by casting, spraying, or doctor blading.

Processes for the manufacture of *inorganic paper* from water-swelling mica gels were developed in the 1960s by the U.S. Bureau of Mines and 3M [19], [20]. These generally rough, porous papers tend to have good strength and handleability. The manufacturing process involves fusion casting of a clear melt, followed by controlled cooling to create large crystalline books of mica. The mica is delaminated and screened, sedimented or decanted to remove the coarse fraction producing a gel from which paper is produced. As in the case of fluorophlogopite manufacture, lack of crystallite size control with concomitant additional processing such as dry milling makes the process expensive.

Figure 4. Physical properties of Macor as a function of temperature.

Lithium magnesium fluorosilicate (fluorohectorite) glass ceramics made by Corning Inc. alleviate a number of the tedious steps associated with manufacture of mica paper, and give a superior, fine-grained product from which smoother paper and film can be manufactured [21–23]. The lithium fluorohectorite crystallites in this glass ceramic consist of tetrahedral sheets of silica interspersed with layers of magnesium atoms octahedrally coordinated to oxygen. One of every four magnesium sites is occupied by lithium requiring an exchange of fluorine for oxygen to maintain charge balance.

The benefit of using a glass ceramic lies in the ability to control nucleation and crystal growth resulting in a uniformly fine-grained mica ceramic that disintegrates in water to give 10 µm particles. The critical issue in using glass ceramics lies in minimizing the amount of glassy, nonmicaceous phases, while promoting mica crystal growth and maintaining good dispersing properties in water. The prime benefit of using a glass ceramic is that it bypasses mechanical grinding, enabling the expedient processing of a stable gel of dissociated mica laminae. Electron micrographs indicate interlacing crystallites less than 10 nm thick and about 10 µm in average diameter.

The solid to liquid ratio of a fluorohectorite mica gelled suspension, its viscosity, and pH

may be controlled and allow a variety of forming techniques. Conventional fourdrinier process papermaking or film extrusion equipment can be used to form large continuous sheet ceramic paper. The gels can also be extruded as fiber. By addition of controlled concentrations of dissolved electrolytes the gels can also be flocculated, hence enabling the manufacture of foamed, spray dried, or cast thick-walled articles. Potential uses for fluorohectorite mica ceramics include dielectric and microwave transparent papers, boards, and cloths; floor tiles; and cheap, lightweight, disposable dinnerware [24], [25].

1. Introduction

The term microbiocide (or more simply biocide) is used to describe all agents that kill microbial life and thus includes antibiotics (→ Antibiotics), antimicrobial agents used in medicine (→ Chemotherapeutics), disinfectants (→ Disinfectants), and agricultural fungicides (→ Fungicides, Agricultural). This article will, however, deal mainly with the compounds used to prevent microbial growth in industrial products, particularly in the food industry, in cosmetics, pharmaceuticals and toiletries, in paints and plastics, in water cooling systems, and in paper manufacture. The use of microbiocides in wood preservation is discussed elsewhere (→ Wood Preservation).

History. Chemicals have been used since the very earliest times in the prevention of disease and the preservation of food. Notable examples were the use of burning sulfur to control the spread of plague and the widespread use of spicing, salting, and smoking to prevent the deterioration of food. The use of chemicals in earlier times was quite empirical since nothing was known about the mechanisms by which they effected the preservation of food or the control of disease. However, these empirical observations were supplemented by a more rigorous scientific investigation following the discovery of the microscope by VAN LEEUWENOEK in the 18th century.

VAN LEEUWENOEK demonstrated the presence of major classes of bacteria, protozoa, algae, and yeasts. The causal relationship between microorganisms and disease was established by the research work of BASSI and PASTEUR on the infection of silk worms by fungi and protozoa, respectively. Major contributions were subsequently made by KOCH and LISTER in the isolation and identification of pure bacterial strains as pathogens responsible for disease. Recognition of the fact that bacteria are responsible for disease and food spoilage created much interest in the development of chemicals for the control of these bacteria. Methods developed by KOCH and others were used in evaluating the effectiveness of these chemicals in destroying bacteria and curing disease. In the latter half of the 19th century, LISTER demonstrated that the use of phenol markedly reduced the incidence of serious infection during surgery. LISTER's work demonstrated the potential of chemical disinfectants in hospitals; subsequently, the use of less toxic and more efficient chemicals was extended to other areas of hospital practice.

The preventative role of chemical biocides was also becoming recognized in the industrial field. The use of biocides in metal working fluids, for example, is an important factor in maintaining product quality and the health of the

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a16_563

work force. In oil recovery, biocides are used to control sulfate-reducing bacteria and to improve yields. In water cooling systems and paper production, added biocides prevent the formation of bacterial or fungal slimes thus avoiding the necessity of costly shut-downs. Generally, microorganisms proliferate in the presence of an aqueous medium and biocides are therefore used in aqueous emulsion paints, polymer emulsions, pharmaceutical products, and toiletries. The microorganism *Cladosporium resinae* can occur in the traces of water found in aircraft fuel tanks and can cause corrosion if not controlled.

Important industrial applications exist for biocides in addition to those normally associated with human and animal health (e.g., hospitals, agriculture, public health and the home; → Disinfectants). Commercially used biocides consist of an active chemical formulated with a solvent or surfactant for direct application. A wide range of chemicals possess biocidal activity and include such diverse groups as phenolics, quaternary ammonium compounds, halogen compounds, aldehydes, alcohols, organometallic compounds, peroxygens, biguanides, and heterocycles.

2. Chemical Biocides

2.1. Phenolics

Phenol [*108-95-21*] itself has little direct use as a disinfectant, but many phenol derivatives, particularly the alkylated and chlorinated derivatives are still widely used.

The high-boiling *tar acids* consist of complex mixtures of alkylated phenols obtained from coal tar by distillation; they are used in the formulation of the so-called black and white fluids. In *black fluids* the tar acids are formulated with castor oil soap and either a neutral or aromatic oil or a cresylic creosote as a solvent or an extender. In *white fluids,* the tar acids are emulsified with either casein or a synthetic detergent. Both fluids are used in agriculture and also as crude domestic disinfectants. A mixture of isopropylphenols produced by the direct alkylation of phenol and marketed by Ciba-Geigy as Alkylated Phenols F 12 is used as a substitute for the tar acids and is marginally more effective.

4-Chloro-*m*-cresol

The bactericidal efficiency of phenol is enhanced by introduction of chlorine atoms and substitution with alkyl or aryl groups (especially if they are ortho to the phenolic group). 4-Chloro-*m*-cresol [*59-50-7*] (PCMC) is used as an antiseptic and disinfectant in the domestic field and in hospitals (as a topical antiseptic). It is produced by direct chlorination of *m*-cresol.

Two powerful disinfectants are derived from 3,5-xylenol by direct chlorination: 4-chloro-3,5-xylenol [*88-04-0*] (PCMX) and 4,6-dichloro-3,5-xylenol [*133-53-9*] (DCMX). The former is used as a topical and urinary antiseptic and is the active disinfectant in Dettol (Reckitt and Colman, UK). The latter, as well as being bacteriostatic in soaps, is also used in domestic pine-type disinfectants.

PCMX

DCMX

2-Benzyl-4-chlorophenol [*120-32-1*] (chlorophene) is produced by reacting benzyl chloride with sodium or potassium phenolate. It is a powerful germicide and an excellent fungicide.

2-Benzyl-4-chlorophenol

2,2′-Methylenebis(4-chlorophenol) [*97-23-4*] (dichlorophen) is synthesized by the acid-catalyzed condensation of formaldehyde and 4-chlorophenol. It is an effective antimicrobial which is used as a germicide in toiletries. It is used in cooling water systems, in the food and oil industries, and in textiles and paper manufacture (trade name: Panacide, BDH, UK). Dichlorophen has a low mammalian toxicity (LD_{50}, rat, oral 2.69 g/kg) and skin irritancy.

2,2′-Methylenebis(4-chlorophenol)

2-Phenylphenol [*90-43-7*] (trade name: Dowicide A, Dow, USA) is a fungicide which may either be synthesized directly or isolated as a byproduct in the production of phenol by the hydrolysis of monochlorobenzene. Direct chlorination of 2-phenylphenol gives a mixture of 4-chloro-2-phenylphenol [*1331-46-0*] and 6-chloro-2-phenylphenol, the former being a very effective biocide which is used as the active ingredient of pine type disinfectant fluids.

4-Chloro-2-phenylphenol

2.2. Chlorine and Chlorine-Releasing Compounds

Chlorine [*7782-50-5*] is widely used in water treatment, particularly in the treatment of crude water before it is supplied for either potable or industrial use. Many cooling circuits in steam electricity generating stations, in food processing plants, and in oil refineries are treated with chlorine to prevent the formation of microbial slimes and to maintain hygiene standards. The bactericidal effect is due to the reaction between chlorine and water:

$$Cl_2 + H_2O \rightarrow HOCl + HCl$$

The non-ionized hypochlorous acid is believed to be responsible for the bactericidal activity of chlorine, hypochlorites, and chlorine-releasing agents. Since hypochlorous acid ionizes to give H^+ and OCl^- ions, the concentration of hypochlorous acid, and hence the bactericidal efficiency will depend on the pH of the solution. The equilibrium diagram for chlorine – water – hypochlorite mixtures (Fig. 1) shows the variation of hypochlorous acid concentration with pH. Hypochlorous acid is believed to react with and inactivate enzymes that are essential for bacterial metabolism, particularly triose phosphate dehydrogenase.

Figure 1. Equilibrium diagram of chlorine – water – hypochlorite mixtures.

Hypochlorites are principally used as the sodium salt [*7681-52-9*] and are cheap, effective biocides that are used widely throughout the EEC in hospitals, agriculture, dairying, food processing, and public health and hygiene. Sodium hypochlorite decomposes with increasing temperature and under the influence of light and certain metallic salts. For this reason the more stable calcium hypochlorite [*7778-54-3*] is used in certain applications, for example in swimming pool disinfection.

The chlorine-releasing compounds are essentially organic chlorine derivatives which are stable when dry, but generate hypochlorous acid in the presence of water. Hypochlorous acid is again the active biocide with the organic substituent controlling its release. Chloramine T [*127-65-1*] (the sodium salt of *N*-chloro-4-methylbenzenesulfonamide) and Dichloramine T [*473-34-7*] *N,N*-dichloro-4-methylbenzenesulfonamide are chlorine-releasing compounds that have been on the market for many years and were used as bactericides during World War I.

Chloramine T

Dichloramine T

Trichloroisocyanuric acid [*87-90-1*] is an important chlorine-releasing agent that is produced by the chlorination of cyanuric acid in caustic soda solution. It finds an important use as a disinfectant/sanitizer in the food industry. A major manufacturer is Chlor-Chem of Hauxton, UK.

Trichloroisocyanuric acid

1,3-Dichloro-5,5-dimethylhydantoin [*118-52-5*] is sparingly soluble in water with which it reacts to give controlled release of hypochlorous acid. 1-Bromo-3-chloro-5,5-dimethylhydantoin [*126-06-7*] reacts with water to form both hypochlorous and hypobromous acids. The latter has a wider pH range of bactericidal activity than hypochlorous acid. When hypobromous acid comes into contact with nitrogenous waste, bromamines are formed which, unlike the chlorine analogues, retain a significant biocidal activity.

2.3. Iodine and Iodophores

Iodine [*7553-56-2*] has a wide range of antimicrobial activity and is effective against gram-positive and gram-negative bacteria, mycobacteria, fungi, and viruses. It also kills bacterial spores after an extended contact time. The active species (the iodine molecule) is only sparingly soluble in water; iodine is therefore used as a solution of iodine in alcoholic potassium iodide.

Iodine stains the skin and may lead to sensitization of the skin and mucous membranes. Iodophores (iodine carriers) were developed in the 1950s in order to overcome these disadvantages. Iodophores are essentially complexes of iodine with various organic compounds which release iodine on demand. The most important complexes used are those with poly(propylene oxide) or poly(ethylene oxide), cationic surfactants (quaternary ammonium salts), or polyvinylpyrrolidone. The iodophores are used in hospitals primarily for skin disinfection, and also in dairy farming where they are important as udder washes in the prevention of bovine mastitis as, for example, the Iosan range of iodophores (Ciba-Geigy, Switzerland) or Iodel FD (Diversey, UK).

$RNH(CH_2)_2NH \cdot (CH_2)_2NH \cdot CH_2 \cdot COOH \cdot HCl$

2.4. Quaternary Ammonium Compounds

Quaternary ammonium compounds are most effective against gram-positive bacteria at concentrations as low as 1 : 200 000. They are less active against gram-negative organisms: concentrations as high as 1 : 20 000 are required to control *Pseudomonas aeruginosa.* Further limitations of quaternary ammonium compounds are their inactivity at and below pH 3.5 and their reduced effectiveness under dirty conditions. They are nontoxic and are used quite widely in hospitals, in the food industry, and as household disinfectants. Commercially important quaternary ammonium disinfectants are benzalkonium chloride [*8001-54-5*], benzethonium chloride [*121-54-0*], and cetylpyridinium chloride [*123-03-5*] (see bottom of the page).

Amphoteric quaternary ammonium disinfectants, usually alkylated aminocarboxylic acid

Benzalkonium chloride

Cetylpyridinium chloride

Benzethonium chloride

derivatives, are also used commercially. The amphoterics have greater caustic stability than the normal quaternaries and are more easily removed from surfaces. This is a great advantage in the food industry where amphoterics are widely used. The formula of Tego 103 S (Goldschmidt, FRG) is given below:

2.5. Biguanides

Although the biguanides had been recognized as biologically active by IG Farben in the 1930s, their potential as active bactericides was first discovered by ICI in 1946 [1], [2] in the form of the biguanide polymer, poly(hexamethylene biguanide)hydrochloride [*32289-58-0*] (PHMB). Subsequently, 1,6-bis(4′-chlorophenyl biguanide) hexane [*55-56-1*] (chlorhexidine) was also found to be a potent biocide. Chlorhexidine and PHMB, are the major biguanide compounds which are used today as disinfectants and sanitizers [3].

Chlorhexidine is bactericidal at concentrations of 100 µg/mL and bacteriostatic at concentrations of 1 µg/mL. It is often formulated with 2-propanol and quaternary ammonium compounds. It is absorbed by the skin and is widely used as a topical disinfectant in hospitals. It is sold under the trade name of Hibitane (ICI, UK) (see below).

PHMB is an industrially important biocide for the control of most gram-positive and gram-negative bacteria, yeasts, fungi, and aquatic algae. It is used in oil recovery, food processing, sugar extraction, and as a disinfectant in swimming pools.

PHMB

Chlorhexidine

2.6. Peroxygens

Hydrogen peroxide and peracids are powerful antimicrobial agents and effective sporicides. A 35 wt % solution of hydrogen peroxide [*7722-84-1*] can be stored for prolonged periods. It is easy to handle, noncorrosive, and mixes readily with water. Hydrogen peroxide is used in hospitals as a topical disinfectant and in swimming pools in conjunction with the ICI product Baquacil (PHMB). It is also important in the control of algae in agriculture and in industrial cooling systems [4].

Peracetic acid [*79-21-0*] and the peracids are nonfoaming, water-soluble liquids which are converted into environmentally acceptable decomposition products, namely, dilute aqueous solutions of the corresponding organic acids. Their bactericidal activity is not affected by hard water and only slightly reduced by the presence of organic matter. An important use for peracetic acid is in the brewing industry.

Trade Name. Proxitane (Interox, UK) [5].

2.7. Alcohols

The aliphatic alcohols, principally ethanol [*64-17-5*], 1-propanol [*71-23-8*], and 2-propanol [*67-63-01*] have long been used as disinfectants in hospitals and medicine. They are active against vegetative bacteria but are not sporicidal. The fact that they are also cleansing agents and are volatile makes them particularly useful in topical applications.

Ethanol is bactericidal at concentrations of 60 – 95 vol % in aqueous solution, but is commonly used at a concentration of 70 % for skin and instrument disinfection and for surface cleaning. It acts synergistically with such bactericides as iodine and chlorhexidine which are frequently used in aqueous ethanol solution. An aqueous 70 % ethanol solution is a powerful virucide and mycobactericide.

2-Propanol is a slightly more effective bactericide than ethanol, but is more toxic. It is also used in preoperative skin treatment.

Other alcohols used as disinfectants and preservatives are phenylethanol [*60-12-8*] and 2-phenoxyethanol [*122-99-6*]. 2-Bromo-2-nitropropane-1,3-diol [*52-51-7*] (Bronopol: Boots, UK) is used as a disinfectant and preservative in pharmaceuticals, toiletries, cosmetics, and household products.

2.8. Aldehydes

A number of aldehydes are antimicrobials but only formaldehyde and glutaraldehyde are widely used.

Formaldehyde [*50-00-0*] is used in the vapor-phase decontamination of infected buildings, particularly in agriculture. It is also used in hospitals as a 37 % aqueous solution with added methanol as a polymerization inhibitor. Formaldehyde is an irritant which exerts a powerful effect upon the mucous membranes, and there has been recent concern about its possible carcinogenicity.

Glutaraldehyde [*111-30-8*], $CHO(CH_2)_3CHO$, is a broad-spectrum bactericide which is also sporicidal. It is most effective at pH 8, but tends to polymerize at this pH. For this reason glutaraldehyde is supplied in acid solution and subsequently buffered to pH 8. It is used in hospitals, particularly in the sterilization of surgical equipment such as endoscopes which cannot be heat sterilized. It is also used as a biocide in the oil industry.

2.9. Hydroxybenzoate Esters

A number of 4-hydroxybenzoate esters are used as preservatives in pharmaceutical emulsions, creams, and lotions, particularly the methyl ester [*99-76-3*] which is more water soluble (0.25 %) than the higher esters.

Trade Names. Nipagin M (Nipa Laboratories, UK), Tegosept M (Thos. Goldschmidt, FRG).

Methyl Paraben

2.10. Heavy Metals

Copper and silver vessels were used in ancient times to prevent the spread of disease through drinking water. Today the best known heavy-metal derivatives used as antiseptics are the organomercury compounds although doubts are raised from time to time concerning their toxicity. Thimerosal [*54-64-8*] is produced by reacting ethyl mercuric chloride with thiosalicylic acid. It is used as a preservative in contact lens solutions.

Trade Name. Merthiolate Sodium (Eli Lilly, USA).

Thimerosal

3. Application of Biocides

A wide range of antimicrobial agents are available as industrial preservatives and biocides (Chap. 2). Their characteristics are sufficiently dissimilar to satisfy the great variety of market niches. Fitting the appropriate biocide into the specific niche should follow a logical selection process. When deficiencies exist, activity can usually be enhanced by appropriate formulation or by using several active agents.

The successful application of selected biocides/preservatives frequently falls short of expectations. Good selection of both agent and concentration is often nullified by poor on-site control. Monitoring strategies are available and deserve wider use. It may well become as important for health and safety reasons to keep in-use concentrations below a specified level as it is to keep them at or above target concentrations.

3.1. Factors Affecting Biocide Selection

The term (micro)biocide inherently implies killing life, preferably microbial life, but it is widely used to include preservatives. Preservatives are merely required to prevent spoilage development and are not expected to sanitize systems that are already infected. Preservatives can also be regarded as biocides – Pharmacopoeia protocols for preservative challenge testing usually demand not only "no increase" but a reduction in viable (culturable) numbers of microorganisms. Speed of action is not essential for preservatives but long-term stability and persistence is (see also → Foods, 3. Food Additives, Chap. 3.1.). Conversely in many practical applications, a fast "disinfectant" action is of prime importance and long-term persistence is of little consequence. The first consideration in the selection of a biocide should thus be its suitability for preservation and/or disinfection. This information should be available in the suppliers' technical data sheets. However the frequently cited minimum inhibitory concentrations are evidence of "no increase", not "kill" and certainly not the rate of kill.

Further selection is an "armchair" exercise using data sheets and published literature to draw up a short list of candidate biocides. This exercise should consider:

1) The biological spectrum of biocide activity – what are the likely short-term and long-term contaminating organisms? Is the biocide effective against them? Organisms occurring as a "biofilm" are much more resistant to biocides than organisms in suspension. Physiologically active organisms are generally more sensitive than "resting" organisms. Killed organisms may still be detrimental if the biocide does not inactivate their enzymes.
2) The influence of product pH on biocide solubility, stability, and activity.
3) The presence of two phases: the biocide will partition between the two according to its relative solubility. Biocide in an "oil" phase is not immediately available to exert its antimicrobial effect in an associated water phase.
4) Environmental impact and toxicology. There must be an acceptable method for disposing of the biocide. All biocides are toxic to humans and thus invoke a risk assessment for their application under the 1988 COSHH regulations [6].
5) Presence of known biocide inactivators or potentiators in the product to be protected.
6) Undesirable effect on the product, e.g., color, smell, pH shift, chemical reactivity, viscosity, flash point.
7) The influence of biocide concentration on activity (concentration exponent). Activity is not usually directly proportional to concentration. For example, reducing phenol concentration by a half would reduce its rate of action 64 fold (the concentration exponent of phenol is 6).
8) The influence of temperature on biocide activity and stability. Increase in activity is usually regulated by the formula

   $$t_1 = t_2 \theta^{(T_2 - T_1)}$$

   where t_1 and t_2 are times to kill, T_2 and T_1 are temperatures (in °C), and θ is a temperature coefficient. For example if θ is 3 (phenol), a 10 °C rise in temperature increases the kill rate 59 000 fold.
9) Ability to monitor active biocide concentration and hence determine "shelf life" or in-use "contact time".
10) Physical properties (powder, liquid, granules, volatility, etc.) which affect handling and measurement.

There is no simple, single, universally applicable biocide. No biocide is likely to satisfy the required specifications and the final choice will be a compromise. Deficiencies can to some extent be compensated by stabilizers, odor masks, dispersants, and combination with other biocides. Technical assessment will then be balanced against cost effectiveness and the final choice may be deferred until laboratory or field trials have been conducted.

Legal regulations vary nationally depending on the nature of the biocide, its formulation, and field of application. Much useful information on the practical application of biocides can be found in the Report of the Expert Advisory Committee on Biocides [7].

3.2. Challenge Testing

Following the armchair selection process, one or more biocides are listed as potentially cost-

effective candidates. Confirmation or final selection probably proceeds based on challenge testing. A great variety of test methods are available from national organizations (e.g., BS, ASTM, Féderation Industrielle Pharmaceutique, Pharmacopoeias). They may not provide the exact required protocol and are frequently modified.

Test methods are divided into two groups according to whether disinfection or preservation is the objective.

Disinfection Challenge Testing. Conventional disinfectant tests for public health microbiology are rarely adapted for industrial purposes but similar principles are involved:

1) A substantial challenge is used.
2) An effect is required in a short contact time.
3) Antimicrobial activity is terminated by the addition of a neutralizer.
4) Action takes place in an unfavorable environment.
5) A quantitative "kill" is determined.
6) The "challenge" is repeated.

Repetition of the challenge is not always necessary for industrial applications. The contact time for public health applications is usually a few minutes whereas several hours are normal in industry. The challenge usually consists of one or more well-standardized pure microbial cultures of public health interest; a mixed inoculum (possibly a previously spoiled sample) is more relevant in industry.

Public Health disinfectant tests are suspension tests. A suspension of test organisms is mixed with the test solution and the number of surviving organisms is determined after certain exposure times. This test forms the basis for the classic disinfectant assays such as the phenol coefficient test [8], the Rideal – Walker test [9], Chick – Martin test [10], the Kelsey – Sykes test [11], the AFNOR test [12], and the 5-5-5 test [13]. In industry it is often as important to kill biofilms, particularly if sulfate-reducing bacteria are to be eradicated. The protocol chosen to evaluate a biocide may include a sequence which confirms efficacy against microbes that are entrained in a biofilm.

Preservation Challenge Testing. Simple preservation tests merely establish "no increase" in the number of microorganisms. More elaborate tests appear in the Pharmacopoeias for Group 2 pharmaceuticals and demand a mixture of "no increase" results and specified logarithmic reductions of microbial numbers. The principles of the best protocols are:

1) A small challenge is used.
2) Surviving organisms are determined several times over a long contact time (days, weeks).
3) A neutralizer is used before testing for survivors.
4) Known species from a wide spectrum of microorganisms are inoculated separately.

For industrial purposes repetition of the challenge is often desirable to simulate potential contamination when a container is opened, partly used, and resealed. The inoculation range may also be extended by including "wild" strains of known significance or mixtures of organisms.

Simulation Tests. Simulation tests mimic real situations on a laboratory scale. The paint industry has possibly progressed furthest in simulation tests to evaluate paint film "fungicides". The deactivating mechanisms of water leaching and UV degradation have been intensively studied, the principle colonizing organisms are known, and thus reasonable simulation regimes can be standardized. For other biocide applications a myriad of simulation devices and procedures have been described. Those for metal working fluids have been the subject of much ingenuity because metal working fluid systems are complex and exhibit marked oxygen, temperature, and Eh (redox potential) gradients; procedures are reviewed in [14]. Biofilms develop slowly; various strategies have been adopted for growing them so that antimicrobial agents can be properly evaluated as regards their penetration of preformed films and their inhibition of film formation. Some procedures are simple and inexpensive [15] whilst others attempt to produce 'standard' biofilm replicates to improve comparison of results [16].

Legionella pneumophila is often a specific target organism in cooling tower water and simulators for this application have been described [17].

Whatever simulation regime is adopted, pass and fail criteria have to be imposed. These may relate to the expected shelf life or in-use life of

the product to be protected and to the anticipated degree of contamination. Although these tend to be arbitrary, the experienced tester is able to rank competitive biocides with a great deal of confidence.

3.3. Spoilage

Spoilage occurs in a wide range of physical and chemical conditions. For a detailed discussion of biodeterioration, see [18–25].

In approximate descending order of importance with regard to volume of biocide sales (not economic consequences) the industries involved are principally: surface coatings, paper, timber, textiles, adhesives and sealants, oil-field, water treatment, metal working, cosmetics and toiletries, fuel, and leather.

Within each industry, a multitude of applications exist for biocides. In some applications the antimicrobial agent (e.g., formaldehyde) is a one-shot treatment and is incorporated into the product during manufacture. When the agent fails, the product fails. In a large number of applications antimicrobial activity can be "topped up" by a tank-side addition when a product is in use. The agent used is frequently different from that originally incorporated in the product and should correct developing spoilage, fouling, or microbial corrosion. It should persist for some time, exerting preservative properties. Although "top-up" can be carried out at arbitrary intervals, this involves the risk of underdosing and loss of control, or overdosing and potential risks for health and environment. Regimes for semicontinuous addition of biocide utilize some form of monitoring.

3.4. Monitoring

Three principal strategies are used for monitoring the effectiveness of biocides: (1) subjective and functional criteria, (2) determination of microbial population, and (3) determination of biocide or preservative concentration.

Subjective and Functional Criteria. In this strategy the effectiveness of the biocide is assessed by means of the effect it produces: prevention of discoloration, visible slime formation, filter plugging, change in pH, corrosion, and system malfunctions. Although crude, this method is still widely practiced.

The procedure necessitates the addition of high biocide concentrations and results in the production of a large amount of dead microbial material and endotoxins. A partially spoiled system cannot be improved, further deterioration is merely delayed.

Monitoring Microbial Populations. In this method the number of microorganisms present in the system is determined; it attempts to arrest a developing spoilage situation instead of preventing it. Biocide depletion or failure is assumed if microbial regrowth is demonstrated.

The reappearance of a potential spoilage flora may, however, also be due to the arrival or generation of microbes resistant to that biocide; a new biocide must then be used. If the microbiological test procedure is based on culturing to yield visible growth, there is a time lag of 1 – 3 days before a result is available; during this time a situation may continue to deteriorate. A false low or negative microbiological result may be obtained due to carry-over of active residual biocide onto the culture medium. To avoid delays, on-site microbiological tests are widely used for semiquantitative results. Traditional laboratory techniques are justified if accurate numbers and identities are needed.

Limit values must be set which trigger an appropriate response. For example a total bacterial count of 10^5/mL and/or the detection of sulfate-reducing bacteria could invoke an addition of the original biocide. The detection of molds and/or yeasts in a system prone to bacterial spoilage could initiate the addition of a different, antifungal agent.

Prior to the introduction of the "Red Spot" test in 1967, there were virtually no practical onsite procedures for quantifying bacterial numbers [26]. This test utilizes the ability of microorganisms to reduce a colorless tetrazolium salt to red formazan. In 1971 the Methylene Blue Reduction Test for quantifying milk microorganisms was applied to metal working fluids [27]. This test exploits the ability of some microorganisms to reduce the blue dye to a colorless base. Din slides, developed in 1975, can distinguish between bacteria, yeasts, and molds semiquan-

titatively and are simple to use on-site [28], [29]. Individual invisible microbes reproduce on the agar surface of the slide to yield visible, countable colonies.

Interpretation of the results is sometimes suspect if the calibration data supplied for aqueous fluids are applied to fluids of differing viscosity and "wettability" such as diesel fuels and lubricants.

A new concept for on-site use, the Sig Test, was described in 1984 [30]. The most useful industrial versions rapidly and semiquantitatively detect nitrite-utilizing and sulfide-generating bacteria. A detecting gel in a tube is flooded with the test sample and undergoes characteristic color and consistency changes.

Rapid instrumental methods such as measuring ATP or impedance are popular in the food and water industries. The impedance test relies on the electrical changes that occur when microbes grow in a culture medium [31]. Problems occur, however; for example, residual biocides may quench the enzyme reactions in ATP-measuring devices; industrial samples, particularly emulsions, may mask impedance changes due to microorganisms.

Monitoring Biocide or Preservative Concentration. The concentration of biocide is not linearly related to its activity (see Section 3.1). A small reduction in the target concentration of a biocide may have a considerable impact on the ability to resist a microbial challenge. In many cases the correct initial concentration is not even achieved due to a lack of knowledge of the system size, of the active concentration of the agent, or of its partition between oil and water phases.

The advantages of monitoring biocide concentration are that biocide concentration can be frequently adjusted and spoilage is prevented not "corrected". If coupled to microbiological tests a realistic "target" biocide concentration can be established and maintained. Biocides can be measured in a number of ways.

Simple colorimetric assays for formaldehyde released from donor biocides have been available for some years (e.g., E. Merck, Darmstadt, FRG) but are not widely used although they are suitable for on-site use. Many simple colorimetric test kits are also available for measuring free and/or combined chlorine but they do not necessarily reflect activity.

Chemical and physical assays for other biocides usually necessitate inital extraction and/or concentration followed by analysis using procedures such as HPLC. The determination may not correlate with known antimicrobial activity, particularly if more than one active agent is present or if biocide activity is potentiated by a formulated component. The techniques are not suitable for on-site use.

Figure 2. Survival curve of *Pseudomonas aeruginosa* for assaying biocides in metal-working fluids
A preserved 3 % cutting oil emulsion was held at 30 °C and 20 mL aliquots removed after 0, 3, 7, and 14 days; 0.1 mL of a suspension of an overnight culture of *P. aeruginosa* was added to the aliquot on removal and the numbers of survivors were determined after 0, 2, 4, and 6 h

A variety of biological techniques are available for assaying antimicrobial activity, they all

involve the inhibition of growth of a sensitive microorganism.

In 1982 a biological method of assaying biocides in metal-working fluids was proposed, which involved challenging aliquots of the preserved metal-working fluid at various storage or in-use time intervals with a standard inoculum of *Pseudomonas aeruginosa* and determining the survival curve over a 6-h period (Fig. 2) [32]. The procedure was relative rather than absolute; comparison of the survival curves revealed biocide depletion or inactivation.

A much simpler biological assay was proposed for metalworking fluids in 1986 [33] and for fuel water bottoms in 1987 [34] (Biocide Monitor, ECHA Microbiology, Cardiff). Spores of a *Bacillus* sp., dried nutrients, and a tetrazolium salt (as a growth indicator) were carried on a pad mounted on a 5×55 mm plastic strip. This was dipped briefly into the test fluid and incubated overnight at 37 °C. Reduction of the tetrazolium to red formazan accompanied spore germination and growth and thus indicated the presence or absence of a chemical inhibitor. The strip could be calibrated against known biocides and biocide mixtures. The minimum inhibitory concentration (MIC) so determined could then be utilized to assay unknown biocide concentrations by establishing which dilution of a sample just contained the MIC. A simple calculation then yields the concentration of biocide present.

Using this device it is relatively easy to determine whether target biocide concentrations have been achieved and are being maintained.

3.5. Predetermined and Automatic Biocide Additions

It is often argued that any form of monitoring is not financially justified for small systems. A compromise is to set up a top-up dosing regime based on an initial monitoring period, preferably based on monitoring the biocide (preservative) concentration (Section 3.4).

Automatic dosing via proportioning pumps has been very successful in systems where there are large volume losses. Cooling water systems are an example of such a system; losses are due to evaporation, misting, and bleed-off. The bleed-off may be triggered automatically by setting a limit value for conductivity which increases due to evaporation losses. The make-up flow is measured and linked to a proportioning pump which doses biocide to achieve a predetermined concentration. The whole system must be dosed with biocide before operation commences.

1. Introduction

Microparticles can be classified into microparticles in the literal sense and microcapsules. With microparticles, the active ingredient is dispersed/dissolved in the carrier matrix (matrix system), while with microcapsules, the active substance is surrounded by a membrane (reservoir system). Microparticles range in diameter from ca. 1 to 1000 µm, although at the upper end of this size distribution, the classification of the particles as microparticles becomes open to question. Nanoparticles are particles in the submicron range. Most gaseous, liquid, and solid materials – whether hydrophobic or hydrophilic – can be encapsulated. The wall/carrier material and also the process of microencapsulation are selected according to the physical properties of the core and the intended appliation. The carrier material generally consists of natural or synthetic polymers or lipids [1–3].

Microencapsulation can modify the color, shape, volume, apparent density, reactivity, durability, pressure sensitivity, heat sensitivity, and photosensitivity of the encapsulated substance. The microcapsule is able to preserve a substance in a finely divided state, and release the substance from the enclosed capsule as required. Encapsulation of a liquid effectively converts the liquid to a fine powder solid form, whilst preserving the reactivity of the interior phase. Microencapsulation therefore improves the "ease of handling" of the liquid reactants, and allows chemical reaction to commence when the microcapsule is ruptured. The density of a substance can be increased by encapsulation, and can be decreased by including air in the capsule. A dense solid can thus be converted by encapsulation into a product which will float on water.

Microparticles have many useful functions, and have been employed in many different areas, frequently connected with applications in which the contents of the microcapsule are released under controlled conditions into the surrounding environment. Sometimes, however, a core material to be enclosed is microencapsulated and then used directly in the powdered form [4–22].

The storage life of a volatile compound can be increased markedly by microencapsulation. Microcapsules can protect a core substance from the effects of UV rays, moisture, and oxygen. Chemical reaction between two active species can be prevented by physical separation by microencapsulation. Finely divided powders can be microencapsulated to reduce agglomeration problems.

The techniques and practice of microencapsulation cover several scientific disciplines, including colloid and physical chemistry, polymer chemistry and physics, materials science, suspension and drying technology, and, in controlled-release applications, pharmaceutical and agricultural technology. Many of these interact with each other in practical applications, and in the resulting commercial implications [4–8].

Most of the possible deficiencies in microcapsules depend on the properties of the wall materials. Premature failure of the microcapsule wall in service before the required conditions for rupture are achieved can cause diffi-

culties, which must be considered in the design of the microcapsule wall system. Many of the more recent developments in microencapsulation technology have been directed at improving the physical properties of the wall polymers in service, so that the microcapsules do not release the core contents, without rupture or leakage, until required.

The design of a microencapsulation system must take into account the total system: the active and carrier materials, the mechanism of release, and the ultimate fate of all the ingredients. Each of these parameters must be optimized if a satisfactory product is to be obtained. Many methods exist for production of microparticles which allow many variations, depending on core and wall-polymer solubility, capsule size, wall thickness and permeability, type and rate of release of core contents, and physical properties.

In choosing processes for the production of microcapsules for particular applications, several physical properties must be considered, including:

1) *Core Wettability.* The key property is the ability of the core to be wetted by the wall material. In principle, this property can be predicted, but, in practice, it is usually determined during the microencapsulation process.
2) *Core Solubility.* The contents of the microcapsule core should not be soluble in the solvent for the wall polymer, and the polymer should not dissolve significantly in the liquid core. With spray coating, a water-soluble solid can be coated with a water-soluble polymer solution, because the water evaporates rapidly during microcapsule formation.
3) *Wall elasticity* is determined by the nature of the wall polymer, its thickness, and the size of the microcapsules formed.
4) *Wall permeability* determines whether the microcapsule core contents can be retained indefinitely (impermeable wall) until ruptured, or may be released at a predetermined rate (permeable wall) as in controlled-release applications.
5) *Wall polymer adhesive characteristics* are markedly affected by solution temperature and concentration, and depend on the physical properties of the wall polymer, notably the melting point and glass transition temperatures, degree of crystallinity, and degradation rate (under microcapsule formation conditions). Stickiness during capsule formation, and "stringiness" during spray drying can be major problems affecting microcapsule manufacture and storage behavior.

2. Reasons for Microencapsulation

The principal reasons for using microencapsulation are listed below.

Controlled Release. Release of the active component is controlled by the carrier material, various release profiles can be obtained. Many of the actual or potential uses of microparticles can be found within this category, usually with additional functional requirements.

Protection of Core Contents Against Atmospheric Effects. Vitamin A palmitate (widely used as an animal feed additive, especially for egg-laying hens), for example, is microencapsulated with gelatin to increase resistance to moisture and atmospheric oxygen, and therefore improve stability. Other fat-soluble vitamins are similarly treated. Microencapsulated feeds are used in industrial fish farming. These are basically high protein – fat mixtures which are microencapsulated to reduce oxidation of the product during storage, and to delay the rate of release into the aqueous environment of the fish farm. Such protection greatly increases the feeding efficiency and growth rate of the fish. Many flavors and fragrance compounds (e.g., methyl salicylate and peppermint oil) can be prevented from evaporating by microencapsulation.

Protection of Hygroscopic Core Contents. The flow properties of mixtures of the hygroscopic B group vitamins (e.g., thiamine hydrochloride, riboflavin, and niacin) with iron phosphate are improved by microencapsulating them before they are compressed into tablets. Choice of suitable coating materials can improve the performance (in compaction and disintegration) of tablets made from encapsulated drugs.

Reduction of Health Hazards. Pesticides are often encapsulated to reduce the hazard

to the user. The antibiotic ampicillin has been microencapsulated to reduce the possibility of sensitization of factory staff.

Reduction of Gastrointestinal Irritation. Encapsulation of drugs [e.g., iron(II) sulfate, acetylsalicylic acid] reduces gastrointestinal irritation by controlling the rate of release into the digestive system. Enteric polymers, for example, do not release the drug in the low pH environment of the stomach, but in the intestine. Gastric upset can therefore be avoided.

Masking of Taste and Odor. Microencapsulation can be used to disguise the unpleasant taste or odor of compounds such as pharmaceuticals. However, taste masking can also be achieved at lower cost by packaging pharmaceuticals in hard gelatin capsules, or by incorporating the unpleasant compound in sugar- or film-coated tablets.

Odor Release Control. In general, the same considerations apply as in masking. However, in addition to protection and reduction of core volatility, the principal use of microencapsulation for perfume-like materials has been in the preparation of "scratch-and-sniff" coatings which can be applied by printing techniques to advertising material. Upon rupture of the microcapsules by mechanical scratching, an odor related to the product being advertised is released.

Masking of Core Properties. The chemical properties of the microcapsule core (e.g., pH or catalytic properties) can be masked until release is required. The major application of this type is the control of the color change of leuco dyes upon pH change, which is the basis of carbonless copy paper.

Separation of Incompatible Components for Functional Reasons. An example of this application is the use of microencapsulated free-radical catalysts (e.g., benzoyl peroxide) mixed with curable polyester resins, which harden in situ at the point of use.

Other Reasons. Other reasons for microencapsulation include the protection of the active component from physical damage and conversion of a liquid active compound into a fluidized "solid powder" form. The latter is sometimes employed with food additives, so that the active component (e.g., a flavor oil, or a bakery additive) can be evenly distributed in a dry powder mix.

3. Materials

Core Materials. A wide range of materials have been encapsulated. These include:

Solvents: benzene, toluene, cyclohexane, chlorinated phenyls, paraffins, esters, ethers, alcohols, and water.
Plasticizers: citrate-, phthalate-, adipate-, and phosphate-type, silicones, and chlorinated hydrocarbons.
Acids and bases: boric acid, caustic alkali, and amines.
Catalysts: curing agents, oxidants, free radical initiators, and reducing agents.
Colorants: pigments and dyes, especially leuco dyes for carbonless copying papers.
Adhesives: polysulfides, cyanoacrylates, isocyanates, epoxy resins, and thermally-sensitive adhesive compositions.
Fragrances: menthol, essences, and specialty compositions.
Foods: oils, fats, spices, and flavors.
Pharmaceuticals: aspirin, vitamins, and peptides/proteins.
Agricultural chemicals: herbicides, insecticides, and fertilizers.
Recording materials: reprographic toners, coupling agents, developers, silver halides, fixing agents, photochromic compounds, and liquid crystals.
Rust inhibitors: zinc chromate and other compounds.
Others: detergents, bleaches, and fire retardants.

Wall Materials. Wall materials [22] may be natural, semisynthetic, or synthetic:

Natural Materials: gum acacia (gum arabic), agar, agarose, maltodextrins, sodium alginate, calcium alginate, dextran, fats and fatty acids, cetyl alcohol, milk solids, molasses, gelatin, gluten, albumin, shellac, starches, caseinates, stearins, sucrose, and waxes (e.g., beeswax, carnuaba, and spermaceti).

Semisynthetic Materials: cellulose acetate, cellulose acetate butyrate, cellulose acetate phthalate, cellulose nitrate (collodion), ethylcellulose, hydroxypropylcellulose, hydroxypropylmethylcellulose, hydroxypropylmethylcellulose phthalate, methyl cellulose, sodium carboxymethylcellulose, hydrogenated tallow, myristyl alcohol (1-tetradecanol), glyceryl mono- or dipalmitate, hydrogenated castor oil, glyceryl mono-, di-, or tristearate, and 12-hydroxystearyl alcohol.

Synthetic Materials: acrylic polymers and copolymers [e.g., polyacrylamide, poly(alkyl cyanoacrylate), and poly(ethylene – vinyl acetate)], aluminum monostearate, carboxyvinyl polymers (Carbopol), polyamides, poly(methyl vinyl ether – maleic anhydride), poly(adipyl-L-lysine), polycarbonates, polyterephthalamide, poly(vinyl acetate phthalate), poly(terephthaloyl-L-lysine), polyarylsulfones, poly(methyl methacrylate), poly(ε-caprolactone), polyvinylpyrrolidone, polydimethylsiloxane, polyoxyethylenes, polyesters, polyglycolic acid, polylactic acid and copolymers, polyglutamic acid, polylysine, polystyrene, poly(styrene – acrylonitrile), polyimides, and poly(vinyl alcohol).

4. Production

Microencapsulation Methods. Many different methods have been proposed for the production of microcapsules (several hundred methods/modifications have been identified in the patent literature) with many variations in detail, depending on core and wall-polymer solubility, particle size, wall thickness and wall permeability, type and rate of release of core contents required, physical properties, and detailed and overall economics of manufacture. The choice of a particular preparation method and a suitable polymer will depend on the physicochemical properties of the active substance, the desired release characteristics, the therapeutic goal for drug substances, the route of administration, the biodegradability/biocompatibility of the carrier material and regulatory considerations. From a technological point of view, the successful selection of a preparation method will be determined by the ability to achieve high loadings with the active substance, high encapsulation efficiencies, high product yields, and the potential for easy scale-up. For example, methods with high encapsulation efficiencies but with only low active loading capacity are limited to very potent active subtances.

The preparation of colloidal carrier systems, such as polymeric nanoparticles, generally also belongs to the area of microencapsulation (Chap. 5). Microencapsulation methods can be classified into the following groups (see also Table 1):

1) Phase separation (Section 4.1)
2) Interfacial and in situ polymerization (Section 4.2)
3) Spray drying, spray congealing (Section 4.3)
4) Solvent evaporation (Section 4.4)
5) Coating (Section 4.5)

Table 1. Microencapsulation processes

Mircoencapsulation process	Core material	Approximate particle size, µm
Phase separation (coacervation)	solids, liquids	2 – 1200
Interfacial polymerization	solids, liquids	2 – 2000
Spray drying and congealing	solids, liquids	6 – 600
Solvent evaporation	solids, liquids	5 - 500
Centrifugal extrusion	solids, liquids	1 – 5000
Air suspension	solids	35 – 5000

Alternatively, encapsulation methods may be classified according to the nature of the suspending medium (liquid or vapor):

Liquid Suspending Media. If a liquid is used as a suspending medium, microencapsulation is achieved by emulsification or dispersion of two or more immiscible phases. These methods involve:

Complex coacervation
Polymer – polymer incompatibility
Interfacial polymerization
In situ polymerization
Desolvation
Solvent evaporation from emulsion
Gelation
Pressure extrusion
Supercritical fluid technology

Vapor Suspending Media. If the vapor is the suspending medium, the microcapsules are formed by atomization of a liquid phase; methods include:

Spray drying and congealing
Fluidized-bed process (including Wurster process)
CoextrusionVvacuum coating
Gelation
Electrostatic deposition

Most microencapsulation systems employ a combination of several processes. In choosing processes for particular applications, the physical properties of the system must be considered.

Microparticle Size and Quality. Many factors affect the size and quality of microparticles. Some of these influence the performance of controlled release of drugs and active components in other applications (e.g., pesticides and aromas).

Factors affecting the size of microcapsules during production are:

Stirring rate
Solids content of organic phase
Viscosity of organic phase
Viscosity of aqueous phase
Concentration and type of surfactant (if any)
Configuration of vessel and stirrer
Quantity of organic and aqueous phases
Temperature profile during production
Nozzle design

Factors affecting the quality of microcapsules during production are:

Choice of solvent
Mixtures of solvents used
Aqueous solubility of active agent
Rate of solvent removal
Drying conditions
Type and molecular mass of carrier
Crystallinity of polymer

4.1. Phase Separation

Phase separation can be divided into aqueous or organic phase separation, depending on the solubility of the wall material. In phase separation, the core material is first suspended in a solution of the wall material. The wall polymer is induced to separate as a viscous liquid phase (not as a precipitate) by several different methods (e.g., by adding either a nonsolvent for the polymer or salts, by lowering the temperature, or by adding an incompatible polymer). This separation process is known as coacervation. Coacervation is recognized by the appearance of turbidity, droplet formation, or actual separation of liquid layers [23–25]. Coacervation may be simple or complex, or may occur as a result of a salting out effect.

Simple Coacervation. In simple coacervation, addition of a water-miscible nonsolvent (e.g., ethanol) to an aqueous polymer solution causes formation of a separate polymer-rich phase due to a partial miscibility effect. An example of a simple coacervation system consists of water, gelatin, and ethanol. The system is, however, difficult to control, and the core material must be insoluble in both ethanol and water.

Typical aqueous polymer solutions and the appropriate nonsolvents are:

Gelatin	ethanol, acetone
Agar	acetone
Pectin	dioxane, 2-propanol
Methyl cellulose	acetone
Poly(vinyl alcohol)	1-propanol
Fibrinogen	1-propanol

An example for organic phase separation is the microencapsulation of water-soluble organic compounds which can be finely dispersed in a solution of cellulose acetate butyrate [*9004-36-8*] (CAB) in methylene chloride. Toluene (a nonsolvent for CAB) is slowly added, causing coacervation of the polymer around the emulsified droplets of the aqueous solution of the organic compound as it separates from solution. The capsule walls can then be hardened by addition of an aliphatic hydrocarbon solvent with a low solvent power (e.g., hexane). Spherical microspheres with thin elastic walls are usually obtained.

Salt Coacervation. In salt coacervation, a polymer separates from an aqueous solution due to "salting out". An electrolyte is added to the aqueous polymer solution so that phase separation occurs. This method can be used to encapsulate water-insoluble oils or dispersed solid parti-

cles. Large amounts of salt are employed, which have to be washed out of the system. Salting out has the limitation that it is difficult to control capsule size and the resulting microcapsules tend to agglomerate. The microcapsules can be stabilized by adjusting the pH or temperature. The methods can be employed with polymers such as gelatin, poly(vinyl alcohol), or anionic polymers such as sulfonated polystyrene, hydrolyzed styrene – maleic anhydride copolymer, starch, or cellulose acetate phthalates. According to KONDO [9], the ranking of the coacervating power for gelatin for different salts is:

1) Addition of cations: $Na^+ > K^+ > NH_4^+ > Li^+$
2) Addition of anions: sulfate > citrate > tartrate > chloride. Sodium and ammonium sulfates are normally employed.
3) Change of pH causing insolubilization and precipitation of polymer.

Encapsulation may be carried out by using a combination of salt and heat with a system based on a mixture of methyl cellulose and carboxymethyl cellulose; the solubility of methyl cellulose decreases with increasing temperature.

Figure 1. Microencapsulation by coacervation
A) Droplets of core material dispersed in gelatin – gum arabic solution; B) Onset of coacervation by separation of finely divided microcoacervates from the solution; C) Gradual separation of the microcoacervate on to the surface of the core material droplets; D) Coalescence of the microcoacervate into wall material of the droplets

Complex Coacervation. Complex coacervation results from the mutual neutralization of two or more oppositely charged colloids in aqueous solution. For example, the positively charged gelatin (pH < 8) forms a complex coacervate with negatively charged gum arabic.

Complex coacervation is closely related to the precipitation of colloidal material from solution: coacervation immediately precedes precipitation. Microencapsulation by complex coacervation consists of three stages (Fig. 1):

1) Dispersion of the active component to be encapsulated into an aqueous solution of a polyelectrolyte;
2) Deposition around the core material of the coacervate formed by addition of an aqueous solution of a second electrolyte of opposite charge; and
3) Gelation of the coacervate.

This principle of phase incompatibility has also been used for production of microcapsules based on the incompatibility of different polymers. Polymer – polymer incompatibility depends on the free energy of mixing of the polymers. An example of this system is the encapsulation of coffee flavors shown in Figure 2. The components are emulsified to form microcapsules, and then stabilized by addition of a hydrocarbon oil and a dehydrating liquid.

The complex coacervation process was originally developed in the 1950s for the coating process used in the manufacture of "no carbon required" carbonless copying paper by the NCR Company (Appleton, Wisconsin, USA) using the protein gelatin and the carbohydrate gum arabic as the electrolyte components [26].

In carbonless copying papers, the contents of the microcapsule core are released by mechanical action when the paper is struck with a typewriter key. These contents consist of a leuco dye (e.g., crystal violet lactone; → Cationic Dyes, Chap. 2.2.) which changes color due to the pH change occurring when it interacts with the acid clay coating of another face of the paper. In terms of volume, carbonless paper copying systems are by far the largest market for encapsulated products, although other processes, apart from gelatin microencapsulation, are now used for the production of these papers (see Section 4.2).

The dispersion of microcapsules contains an acid-sensitive leuco dye system and is coated on the underside of the top paper sheets. Impact from a writing instrument or type element ruptures the microcapsules, and releases the dye

Figure 2. Flow diagram for encapsulation of coffee flavors [27]

solution. The dye thus comes into contact with the acid clay coating the upper surface of the copying paper and develops its color (Fig. 3).

Figure 3. Three-sheet carbonless copying paper system with microcapsules
a) Paper; b) Acid clay; c) Microcapsule; d) Oil solution of leuco dye

Coacervation is reversible, and in general, the formation of microcapsules by phase separation methods, such as coacervation, is an equilibrium process. For gelatin –gum arabic microcapsules, the equilibrium is stabilized by cross-linking or "curing" the gelatin.

Gelatin with a high isoelectric point (pH 8, normally a pigskin-origin gelatin) and gum arabic are added to a suspension containing the active leuco dye core material at pH 4 – 5. The temperature is maintained above 35 °C to ensure that the coacervate is in the liquid phase. As the positively charged gelatin and the negatively charged gum arabic interact, viscous liquid microdroplets of the polymer coacervate separate. These particles are stabilized (i.e., cross-linked or cured) by reaction with formaldehyde or glutaraldehyde; reaction with $CrCl_3$ or $CuSO_4$; addition of alum; reaction with tannic or gallic acid or their iron salts, as activated phenolics; or heat treatment.

The mixture is then cooled to below 10 °C, adjusted to pH 9 and the microcapsules removed by filtration. In a variation of this process, two different gelatins, prepared by different manufacturing methods from different raw materials, are used as the two polymers.

An example of a simple and reliable method for the laboratory-scale production of microcapsules by the coacervation system is outlined as follows [27]:

1) Add 10 g gelatin to 225 g water, and allow to swell for 15 min.
2) Heat to 42 – 45 °C, and add 100 mL of internal phase (active compound in liquid form or in solution) and disperse to the desired droplet size.
3) Add 10 g gum arabic in 225 g water heated to 42 –45 °C.
4) Adjust pH to 4.5 – 5.5. This will form capsules with a size of 200 – 700 µm. For smaller capsules (30 –100 µm) add up to 700 mL water.
5) Cool to 28 °C with stirring.
6) Cool below 10 °C with ice.
7) For hardening, add 5 mL of 25 % formaldehyde or glutaraldehyde solution. (Use of formaldehyde gives an elastic capsule wall. Use of tannic acid gives a brittle wall.)
8) Wash 3 – 5 times to remove the free coacervate.
9) Add dispersing agent (colloidal silica) and wetting agent.
10) Filter microcapsules.
11) Dry with cool air in a fluidized bed.

4.2. Interfacial and in situ Polymerization

The principal chemical reaction methods for the production of microcapsules involve *interfacial polymerization,* typically between a diacyl chloride and an amine or alcohol. The resulting polymer films may be a polyester, polyurea, polyurethane, or polycarbonate. A range of pesticides have been encapsulated by this method, in which a solution of the pesticide and a diacyl chloride is emulsified in water and an aqueous solution of amine and a polyfunctional isocyanate is added. Upon addition of a base, the microcapsules are formed at the interface between the aqueous medium and the emulsion droplets. The isocyanate acts as a cross-linking agent to reduce the permeability of the capsule walls and to increase their resistance to damage.

Durable, impact-resistant microcapsules with high-tensile-strength walls have been developed for pesticide and pheromone formulations [28].

In the related process of *interfacial coacervation*, a polymer coacervate of an emulsified water-soluble natural extract is emulsified with a cold saturated solution of diethyl ether in water that contains a polyethylenesorbitan ester emulsifer (Tween 20); a collodion solution is then added. The capsule walls are hardened with *n*-butyl benzoate.

In a process developed by 3M, a water-insoluble core material is emulsified into an aqueous solution of a low molecular mass urea – formaldehyde (UF) resin, followed by reduction of the pH to about 1.5 – 3 with formic acid, causing the formation of a UF polymer shell. The microcapsules formed have a diameter of 10 – 50 µm, and have been used in the encapsulation of fragrances for advertising purposes [29].

Methods based on *in situ polymerization* have been employed to prepare microcapsules for carbonless copying paper systems. Condensation polymerization systems are used to form the microcapsule wall polymers that contain the color systems. The principles of carbonless copying paper are described in Section 4.1.

The production of microcapsules for carbonless copying paper using melamine – formaldehyde (MF) and UF resins condensates as wall polymers follows [30–33]:

1) Emulsify and mix aqueous solution of MF/UF precondensates and acrylamide – acrylic acid copolymers with capsule contents (solvent + dye)
2) Add dilution water and stir for 30 min
3) Adjust pH with acetic acid to pH 4.7
4) Maintain at 55 °C for 2 h
5) Cool and stir overnight
6) Raise pH to 10.0
7) Microcapsule mixture ready for coating

The more recently developed carbonless copying paper systems using MF resins and a controlled acid developing system are described in detail in [34], [35]. The polymers used for microencapsulation of the leuco dye comprise methylated MF precondensates with acrylamide – acrylic acid copolymers in aqueous solution. Water-soluble polymers (starch or cellulose ethers) are added as viscosity controllers. The microcapsule leuco dye system is coated on the back of the top paper sheet. The acid component is coated onto the front of the lower sheet of the self-copy system and is based on a dispersed hydrated silica coated with an aluminum salt [36].

The (acid) aluminum compound is distributed preferentially on the surface of the silica, and may be modified with other metal ions. There are further developments, especially with the introduction of improved cross-linking and encapsulating systems for the dyes.

4.3. Spray Drying, Spray Congealing

Spray drying is a very attractive and versatile microencapsulation process for a variety of reasons. Active materials with differing solubility properties can be encapsulated with various wall materials and partitioning of the active substance between two immiscible phases is avoided. In addition, when compared to other multi-step microencapsulation processes, spray drying is a single step operation, which has been scaled up in other industrial applications. In the spray-drying process, a microparticle powder is formed by spraying (atomizing) a solution/dispersion of active material and the film-forming wall material as fine droplets into hot air. The water then evaporates and the dried solid is separated, usually by air separation [9] (see also → Drying of Solid Materials, Chap. 2.1.5.). Several process variables can be important in achieving the desired properties, including the core : wall material ratio, and the concentration, viscosity, and temperature of the starting solution. An aqueous solution, an organic solution, or a slurry of the material to be coated may be used.

Drug-containing biodegradable poly(lactide) microparticles were prepared by spray drying an organic polymer solution [37]. Solvent-free polymeric microparticles were prepared by spray drying an aqueous polymer dispersion, whereby the colloidal polymer particles coalesced into larger microparticles [38].

The design of the spray dryer can be important (e.g., the structure of the drying drum, flow pattern and flow rate of the air current, drying temperature, and type of collector). Some exam-

Table 2. Microencapsulation by spray drying∗ [9]

Core	Polymer solution	Drying temperature (inlet – outlet), °C	Microcapsule size, µm
Water-insoluble polymers			
Liquid paraffin (100)	acetyl cellulose (50) acetone (600)	130	50
Dye solution (50)	zein (40) methanol (200)	130	1 – 60
Carbon black (1)	polystyrene – butyl methacrylate latex (15 %) (16)	95 – 80	7 – 11
Paraformaldehyde (1)	polycarbonate (2) chloroform (100)	110 (steam)	10
Water-soluble polymers			
Liquid paraffin (100)	hydroxyethyl cellulose (150) water (300)	130	5
TiO_2 (200) $CaCO_3$ (385)	polyacrylic acid (325)	50 – 35	2
Choline chloride (63)	clay (11) water (37)	160 – 190	100
Lemon oil (37)	carboxylated dextrin (150)	85 – 38	10 – 20
Dimethyl polysiloxane (50)	methyl cellulose (5) solid milk (45)	265 – 120	100

∗ The figures in parentheses indicate parts by weight.

ples of materials encapsulated by this technique are given in Table 2.

Similar types of spray-drying systems using different operating conditions can be used for microencapsulation of labile materials because of the brief contact time in the dryer. The method has been used to encapsulate fragrance oils, which are emulsified into a water-soluble polymer solution (e.g., with gum arabic) to make fine particles. These are used in products such as bath powders, when the formulation is controlled to release the aroma when the mixture is dissolved.

Spray Congealing. The related spray-congealing process is carried out by mixing the core material with a molten wax or fat. The molten formulation is then sprayed and chilled below its melting point to form particles. The system can be used for microencapsulation of such solid materials as citric acid, vitamin C, potassium chloride, and iron(II) sulfate.

As a drying process, spray drying is relatively expensive, but appropriate variations on the basis principle can be an economic form of production of microcapsules.

4.4. Solvent Evaporation Processes

The solvent evaporation method is a technique widely used for the preparation of biodegradable and nondegradable microspheres [39–41]. In this method, the active material and the polymer are dispersed or dissolved in a volatile, water-immiscible organic solvent (e.g., methylene chloride, chloroform, ethyl acetate). This solution or dispersion is then emulsified in an external aqueous phase containing an emulsifying agent by using conventional emulsification equipment to form an o/w-emulsion. Microspheres with a size range generally between 5 – 250 µm are obtained after solvent evaporation. Depending on the solubility of the active substance, various modifications of the solvent evaporation method exist. A multiple emulsion (w/o/w-method) or an external oil phase can be used for water-soluble active compounds.

4.5. Coating Processes

Small, particulate cores can also be coated by air suspension coating (fluidized-bed coating technologies). In air suspension techniques, particles are suspended in an upward-moving air stream and are coated by spraying polymer solutions or aqueous colloidal polymer dispersions onto the particles.

Equipment for this (and other) types of coating is made by several firms [42], [43]. The most widely used device is the *Wurster coating chamber*. "Combination" sets of equipment can be

modified for use with different coating systems. The equipment is automatically controlled and is designed for safe operation, taking account of the explosive hazard problems of electrostatic charges which can occur in coating systems employing flammable organic solvents with a low boiling point. For this reason, pressure-release devices are normally incorporated into production equipment. It is claimed that air control and powder coating systems provide more uniform film coatings on the active materials. This in turn gives reliable reproduction of predetermined release profiles for controlled-release microencapsulation systems. A typical small-scale fluidized-bed unit for pharmaceutical applications including granulating, drying, and film coating of solids (powders, tablets, and pellets) is shown in Figure 4.

Figure 4. Small-scale general-purpose dryer/encapsulator for pharmaceutical and related products (Glatt AG)
a) Exhaust air filter; b) Spray nozzle; c) Product container; d) Temperature sensor; e) Sample port; f) Drain

Wurster Process. The Wurster process (Fig. 5), developed progressively since the mid 1950s, has been offered in the United States since 1976, and more recently in Europe [43]. It is particularly suited for uniformly coating particles in a single operation. It is used for pharmaceutical products (particularly for controlled release and taste masking), foods, and animal feeds (to improve shelf stability and reduce caking), chemicals (for controlled release and to change surface and adsorption properties), agricultural products (seed coating for easier handling and machine planting), pesticides, nutrients, and rodenticides (for taste masking and controlled release).

Figure 5. Diagram illustrating the Wurster process (Coating Place Inc.)
a) Hydraulic or pneumatic nozzle; b) Controller particle flow; c) Coating partition; d) Coating spray; e) Air flow; f) Air distribution plate

The Wurster system is reproducible and controllable, and can be run on a small as well as on a production-size scale.

The operating chamber is designed to induce a smooth cyclic flow of particles past a nozzle which atomizes the coating solution. The wall material could also be a molten wax (e.g., a fatty material), or dissolved in an aqueous or organic solvent. The coated particles are lifted on the air stream and dried as they rise on the airstream from the nozzle. They then settle out and descend to begin another cycle. The coating film thickness is controlled by the type of coating, the solvent concentration, the air volume and temperature, atomizing conditions, and the number of coating cycles; since many thin coats are applied, the systems can be used with irregularly shaped particles.

Because this process uses large volumes of air, the system has a large drying capacity and the particles are separated as they are carried on the air stream. Small particles can thus be coated with good control of agglomeration.

Suitable coating polymers are offered by Röhm, FMC, Colorcon, or BASF. The release of the active substance can be controlled by several process and formulation variables.

5. Other Forms of Microencapsulation

Nanoparticles are active substance-containing colloidal particles with a size $< 1\,\mu m$. The active compound can be present in various physical states; it can be dissolved in the polymeric matrix, it can be encapsulated, or it can be adsorbed or attached to the surface of the colloidal carrier. The techniques used to prepare nanoparticles are generally classified into two groups. In the first group, nanoparticles are formed from preformed polymers. Alternatively, nanoparticles are prepared by various polymerization reactions of lipophilic or hydrophilic monomers.

Nanoparticles Prepared from Preformed Polymers. Nanoparticles have been prepared from a variety of both water-soluble and water-insoluble polymers of synthetic, semisynthetic, or natural origin. The use of preformed polymers has several advantages as compared to nanoparticles prepared by polymerization of monomers. Advantages include the use of polymers with well-characterized physicochemical properties, established safety and approval standards, the absence of residual monomers or polymerization reagents (e.g., initiators or catalysts) and the lack of possible reactions between drugs and monomers. In addition, it is not possible to obtain nanoparticles by emulsion polymerization in the case of polymers where suitable monomers are not available (e.g., polylactic acid and lactic – glycolic acid copolymers, cellulose derivatives such as ethyl cellulose and cellulose acetate or natural polymers such as gelatin or sodium alginate).

Most techniques to prepare nanoparticles from *synthetic water-insoluble polymers* are derived from conventional emulsification technologies, which have been used to prepare microparticles, such as the solvent evaporation method. To prepare nanoparticles and not microspheres, the o/w-emulsion is homogenized under high shear with an appropriate homogenization equipment (e.g., microfluidizer, sonication) prior to the precipitation of the polymer to further reduce the particle size of the internal organic phase into the colloidal size range [44–47]. Drug – polymer particles in the nanometer size range are formed after solvent diffusion into the aqueous phase and evaporation at the water/air interface causing polymer and drug precipitation. Nanoparticles have been prepared with conventional laboratory homogenizers [44], by ultrasonication [45], [46], [48] or by microfluidization [47].

Hydrophilic polymers are primarily of natural origin. The nanoparticles are prepared either by an w/o-emulsification method or by aqueous phase separation techniques (e.g., coacervation). Preparation of nanoparticles of hydrophilic polymers (e.g., albumin, chitosan, gelatin or carbohydrates) by w/o-emulsification techniques has been developed for the preparation of albumin microspheres [49–52]. Basically, an aqueous polymer solution is emulsified into an external, water-immiscible phase, such as an oil or organic solvent followed by homogenization. Upon water removal, the polymer droplets solidify. Insoluble nanoparticles can be obtained by further hardening/insolubilizing the polymer through chemical cross-linking with aldehydes or other cross-linking agents or through denaturation at elevated temperatures.

Nanoparticles Prepared by Polymerization of Monomers. The methods used to prepare nanoparticles by polymerization are derived from methods developed to prepare latices. The monomer, which are primarily of acrylic origin, can be either dissolved or emulsified in the continuous phase, with the resulting polymer being insoluble in either case. The preparation of nanoparticles by polymerization reactions is generally classified according to the resulting polymer or the resulting particle structure.

6. Characterization of Microparticles

Formulation and process parameters of the described preparation techniques will strongly affect the performance of the microparticles. A precise characterization of the physicochemical

parameters is important in order to develop a product of high quality.

The parameters generally used to characterize microparticles include the particle size, morphology, and surface charge, the drug loading and encapsulation efficiency, the drug release profile, the physicochemical state of the drug and polymer, molecular weight of the polymeric carriers and in vitro biodegradation.

7. Uses

A great diversity of products have been microencapsulated for many different purposes. Only a limited number of these can be described in addition to those already mentioned.

Food Industry. Many foods and animal feed additives have been encapsulated in gelatin and vegetable gums.

Food additives are encapsulated to improve storage life by reducing volatilization and oxidative degradation. However, small amounts of free active material may be released during storage and contaminate the encapsulated product. Spray drying may overcome this problem at the cost of loss of low-boiling volatile components. Alternatively, the mixture may be microencapsulated by extrusion under pressure into alcohol at 100 – 120 °C to solidify the capsules. The resulting particles are larger than those obtained by spray drying, and the process may also adversely affect heat-sensitive components.

Examples of encapsulated food additives include flavors and aromas (such as citrus oils, spices, and coffee oil, see Section 4.1). Bakery flavors (e.g., ethyl vanillin) have been encapsulated in ethyl cellulose and gum arabic. Liquid additives are dispersed as droplets in a matrix of carrier material. Garlic oil has been encapsulated to reduce odor difficulties in handling [53–56].

In animal feeds, microencapsulation is used to protect atmosphere-sensitive additives: the largest application is the coating of synthetic vitamin A with gelatin for use as a poultry feed additive to enhance the color of egg yolk. In addition, microencapsulation is being increasingly used to produce edible microglobules for fish farming. Trout feed, for example, is obtained from gelatin microcapsules that are cross-linked with glutaraldehyde to control the rate of dissolution into water [56]. Uses of such products greatly increases the food conversion and growth rates of farmed fish and crustaceans, notably trout and prawns.

Pigments. Encapsulated pigments (e.g., in cosmetics) have been prepared using acrylic copolymers as the film-forming agents. Polyvinylpyrrolidone has been used as the wall-forming polymer for microencapsulating additives for specialty paints.

Laundry Products. Microcapsules are used in the formulation of laundry products, notably fabric softeners [57], optical brighteners [58], [59], and chlorine donors [59], [60].

Paper. The principal application of microcapsules in the coating of paper is the production of carbonless copying paper (see Section 4.1). Microencapsulated, air-containing opacifiers have also been used to increase the whiteness of the product.

Pharmaceuticals. Microcapsules are employed in many applications in pharmaceuticals (→ Pharmaceutical Dosage Forms). For example, aspirin is coated with ethyl cellulose and other cellulose esters to reduce stomach irritation [61]. Use of cellulose acetate phthalate as part of the capsule wall results in capsules which are insoluble in the acid environment of the stomach and dissolve only at higher pH in the intestines [62].

Of the many drugs based on microencapsulated controlled delivery systems, the "Contac"-type cold-relief remedies (and many similar competitive products) have been among the first products available on the market. The active components (usually phenylpropanolamine hydrochloride [*700-65-2*] and chlorpheniramine maleate [*113-92-8*]) are encapsulated in particles with a range of different sizes. The particles are pan-coated to different wall thicknesses, all contained in a hard-shell gelatin capsule. The particle sizes and coating thicknesses are designed so that the microcapsules dissolve in the digestive system at different rates, and release their active contents over a period of time.

In recent years, biodegradable microparticles based on poly(lactide – glycolide) copolymers

have been developed. These microparticles are used as encapsulation for some peptide drugs.

Cosmetics. Microencapsulation is used in the manufacture of beauty aids, including encapsulated perfumes (delayed release) and cosmetic aids (e.g., make-up removers).

Pest and Weed Control. There have been many applications of microcapsules in agriculture, to improve the delivery of active compounds (i.e., pesticides and herbicides) to the required target organisms. In many cases, microcapsules have been manufactured from specific products for particular uses. Capsule properties (i.e., storage life, and the time and rate of release of active component under field conditions) must be related to the identified biological behavior of the organism (such as a harmful pest or weed) which is to be controlled. Many pesticides have been microencapsulated, including methyl parathion [*298-00-0*], diazinon [*333-41-5*], thiocarbamates, and pyrethrins.

Durable microcapsules have been developed for the sustained and controlled release of biologically active materials, notably pesticides, to provide long-term effectiveness. These microcapsules have an outer wall of gelatin and an inner wall of a synthetic polymer, which may be polysulfone, polycarbonate, poly(methyl methacrylate), or a poly(styrene – acrylonitrile) copolymer. The active components are mixed in dichloromethane with the wall polymer, then emulsified with gelatin and nonionic surfactant at 45 °C until all the solvent has evaporated [63]. This microencapsulation system has been used not only for conventional insecticides (e.g., Naled), but also for the controlled release of pheromones such as " gossyplure" (pink bollworm pheromone) and " disparlure" (gypsy moth pheromone). The main advantage of the system is that the double-walled microcapsules have high impact resistance, and a long storage life compared to those produced by other systems.

Miscellaneous Uses. *Scented strips*, made by coating perfume-loaded microcapsules onto paper, have been widely used for advertising purposes in "scratch-and-sniff" sales promotions. Both gelatin-based and amino-resin-based capsule walls have been used.

Microencapsulated anaerobic *adhesives* are used to coat the threads of bolts and other fasteners. When a nut is screwed on to a coated thread, the microcapsules are fractured, and the adhesive seals the voids, so securing the fastening. Microencapsulated epoxy resin hardeners are also produced for control of adhesive resin setting rates.

Microencapsulation has also been used to encapsulate enzymes and cells (→ Immobilized Biocatalysts, → Immobilized Biocatalysts) and to make artificial cells [64].

Other microencapsulated products include dental amalgams containing encapsulated mercury; photographic materials and temperature-sensitive liquid crystals; tobacco flavors; weather modification systems (using microencapsulated hygroscopic seeding agents); microencapsulated reagents and catalysts; and flame retardants (as components of rigid and flexible foams).

1. Introduction

Milk is the sole source of nutrients for all newborn mammals, including humans, in the first few months after birth. In dairy technology, the term milk refers exclusively to cow's milk that is collected as unaltered mixed milk from a large number of (usually several hundred) healthy cows. Milk from other sources must be labeled according to the species of the animal (e.g., goat's milk). Milk usually delivered at the dairy originates from small herds or from individual cows and shows a somewhat larger variation in properties and composition than mixed milk.

The milk is separated into two fractions (cream and skim milk) by centrifugation or spontaneous creaming. The *cream* is rich in fat, and the *skim milk* is practically fat-free. *Buttermilk* is the liquid remaining when butter is made from cream. The liquid that separates on acid curdling of milk is called *acid whey* and that obtained through rennet curdling is known as *rennet whey*.

A cow can be milked for approximately ten months after the birth of a calf. The composition and properties of the milk change during the course of this lactation period. The colostrum (colostral milk), obtained during the first few days after birth, contains high concentrations of antibodies that protect the newborn calf against infection. Colostrum is unstable when heated and consequently unsuitable for normal consumption.

The production of and trade in milk and dairy products are regulated by national laws and international agreements (Chap. 11).

2. Historical Aspects [1, 5]

The domestication of animals and the consumption of milk and simple milk products by humans probably began about 6000 to 8000 B.C. The Egyptians possessed dairy cattle even in 4000 B.C. and references have been made to milk production in ancient India (2000 B.C.). The milking of cows and the processing of milk, presumably a type of primitive buttermaking, are depicted in a frieze in a Sumerian temple located in the Euphrates valley and dating from 3100 B.C. The ancient Greek art of dairy farming was recorded by HOMER in the Iliad and Odyssey (ca. 900 B.C.) and by other authors such as HERODOTUS and ARISTOTLE. The Romans also practiced dairy farming, as mentioned in the writings of many authors (CATO, VERGIL, and STRABO). In addition to the consumption of milk and butter as food, these products were also used in ancient times for cosmetic and cultic purposes. Numerous references to the high esteem in which milk ("the land of milk and honey"), cattle, and cheese production were held can be found in the Old and the New Testaments. The first descriptions of the production of cheeses such as Glarner Schabzieger, Roquefort, Chester, and Emmentaler date from the 11th and 12th centuries. In the 13th century, MARCO POLO referred to a type of dried milk produced by the Tatars and the Mongols.

It was not until 1541 that K. GESSNER, a scientist from Zürich, wrote a book on dairy farming. Milk was examined scientifically for the first time a century later; the properties of lactose were described in 1633 (F. BARTOLETTI) and the presence of fat globules (A. VAN LEEUWENHOEK) and lactalbumin (TH. A. QUEVENNE) in milk were discovered in 1673 and 1841, respectively.

The Pilgrims of the "Mayflower" did not bring cattle with them when they settled in North America. Cattle were first introduced into the Plymouth Colony in 1624 leading to a great improvement in the settlers' nutrition [1].

The first methods for the conservation of milk were developed in the 19th century. Milk was first sterilized by N. F. APPERT in 1804; the evaporation of milk containing added sugar (NEWTON) was introduced in 1835; and the production of sweetened condensed milk by evaporation under vacuum conditions (G. BORDEN) was carried out in 1853. The first condensed milk factory was erected in the United States (Borden) in 1856, the milk separator was invented in 1859; the year 1866 was marked by the successful pasteurization of milk and by the erection of the first condensed milk factory in Europe (Anglo-Swiss Condensed Milk Co., Cham, Switzerland). The autoclave sterilization of condensed milk was reported in 1885 (J. B. MEYENBERG). The production of dried malt milk was achieved in 1887, the first synthetic resin (galalith from casein) was available in 1897, and the first homogenizer was invented in 1900. The use of a roll dryer for the production of milk powder was introduced in 1902 by J. A. JUST; spray-drying, invented in 1872, was also applied to milk at the beginning

Table 1. Composition of milk of various species * [11, 19, 21, 22]

Main Constituents, g/100 g whole milk	Cow's [11]	[19]	Human [11]	[19]	Goat [11]	[19]	Ewe [11]	[22]	Buffalo ** [11]	[21]
Protein (N × 6.38)	3.3	3.3	1.1	1.1	3.7	3.1	5.3	5.5	4.0	3.6

Carbohydrates	4.8	4.7	7.1	7.1	4.8	4.4	4.7	4.8	5.1	5.5
Organic acids	0.2	0.3								
Minerals (ash)	0.7	0.7	0.2	0.2	0.8		0.9	0.9	0.7	0.8
Sum of solids	12.8	12.7	12.5	12.9	13.2	11.0	17.1	18.7	17.8	17.2
Energy, kJ/100 g milk	280	290	290	310	290	250	400	400	450	440

* Energy content: 17 kJ/g for protein and for carbohydrate; 38 kJ/g for fat; 10 kJ/g for organic acids.
** *Bubalus bubalis* (water buffalo)

of the 20th century. The production of yogurt and processed cheese commenced in Germany in 1907 and in 1911, respectively (Gerber & Co., Thun, Switzerland).

The introduction of stainless steel gave a tremendous boost to the milk industry and resulted in an improvement in the quality of almost all milk products.

The production of sterile consumer's milk with a long shelf life (6 – 12 months) by continuous high-temperature short-time pasteurization followed by aseptic packing has a long history (Section 7.4):

- The first continuous process for sterile milk (USA, Germany) was introduced soon after 1890 [20]
- By 1914 the first patents were granted for the sterilization of milk by spraying with a hot jet of gas or steam [20]
- Direct heating of the milk by steam injection was introduced in 1927 (G. Grindrod, USA)
- Uperization (steam injection 150 °C, 2.4 s) was invented in 1952 [29]
- The Laguilharre process (injection of milk into steam) was introduced in 1954 [30]
- Indirect heating, ultrahigh temperature (UHT), was introduced in 1981 [13, 14, 24].

The technique of continuous heating required the development of methods for filling the product into commercial packs under sterile conditions. Examples of successful processes are:

- 1951, Martin Aseptic Canning System (USA) [31]
- 1961, packs made of coated cardboard (Tetra Pak, Sweden; Alpura Ltd., Switzerland) [32].

3. Composition of Milk [2, 5, 8, 9, 11, 18]

Whole milk is a colloidal system composed of a continuous aqueous phase in which lactose, whey proteins, and minerals are dissolved. The dispersed phase consists of casein micelles (see Section 3.2.3) and fat globules (see Section 3.1.2). Whole cow's milk contains typically 90 g/kg of solids non fat (SNF) and between 35 and 40 g/kg of fat. Both the fat globules and the casein micelles contribute to the whiteness of milk by light scattering.

Removal of the milk fat by centrifugation leads to skim milk on the one hand and to cream on the other.

Cream can be considered as a concentrated dispersion of fat globules.

Skimming of milk results in *skim milk* with $< 0.1\,\%$ of residual milk fat.

The term total solids (TS) refers to all dissolved or dispersed components of milk, it is typically 130 g/kg for pooled cow's milk.

The major constituents of bovine milk and milks from a few other species such as goat, ewe, or buffalo, which are economically significant, show some species dependent variation (Table 1).

Thus, milk from water buffalo is very rich in fat, while ewe's milk is both fat and protein rich, if compared with bovine milk. The composition of human milk is rather unique with respect to its low protein content. Its energy content is similar to that of cow's milk but more energy is derived from fat and lactose than in bovine milk.

There is also some variation in the composition of bulk milk of the same species throughout the milking season and also in dependence of the stage of lactation. The breed of the cow has a marked influence on the composition of its milk.

Table 2. Fatty acid composition of the milk fat of various species

			Bovine milk, % fatty acid in total milk fat			Milk of other species, % fatty acid in total milk fat			
Fatty acid	Symbol	*fp*, °C	Cow's [10]	Cow's [24]	Butter [25]	Human [26]	Goat [24]	Ewe [24]	Buffalo [24]

Linolenic acid	C18:3		1.4	0.8	1.7	1.4		1.4	2.5
Total unsaturated fatty acids, %			33.9	35.3	27.3	55.1	32.9	26.9	37.1

The type of feeding (pasture or other) also influences the composition of bulk milk, especially the protein and fat contents.

3.1. Milk Fat

The milk fat in whole milk is present in form of globules, which are surrounded by a lipoprotein membrane. After its extraction from the fat globules, e.g., in butter production, essentially plain milk fat is obtained, containing some water in form of a water-in-oil emulsion.

3.1.1. Composition [23, 24]

Milk fat is composed to ca. 99 % of neutral lipids. Among these, triglycerides (triacyl glycerols) are the predominant group. Diglycerides (1 – 2 %) and very small amounts of monoglycerides (< 0.1 %), together with some sterols and free fatty acids, complement this fraction.

Complex milk lipids account for about 1 % of the total milk fat and are mainly composed of phospholipids in the following order of abundance:

phosphatidylcholine (lecithin) > phosphatidylethanolamine > other phospholipids

This fraction contains also trace amounts of ceramides and gangliosides.

The fatty acid composition of bovine milk fat is listed in Table 2, and compared with that of the milk fat of other species. Although the total number of different fatty acids in milk fat exceeds 200, only 15 fatty acids are present in important amounts. Bovine milk fat contains a relatively high proportion of saturated fatty acids, a characteristic shared by goat's, ewe's, and buffalo's milk, which contrasts with the relatively high level of unsaturated fatty acids in human milk fat.

The short-chain fatty acids ($C_4 - C_8$) of cow's milk are critical for its taste qualities. Release of short-chain fatty acids by lipase causes rancidity.

The fatty acid profile of milk fat varies depending on season and type of feeding. The degree of saturation, expressed by the iodine number (iodine number = grams of iodine bound per 100 g of fat), is 25 – 30 in European winter with hay feeding, while it is 35 – 40 in the summer season. Parallel with this goes a change in the melting properties of the milk fat. The more saturated winter fat melts at higher temperature than the less saturated summer fat. Above 35 °C, milk fat is completely liquid. At room temperature, the solid fat fraction amounts to about 20 % and this value increases at refrigerator temperature (4 – 6 °C) to about 50 % (see Section 9.6.2).

3.1.2. Properties of Fat Globules

Whole cow's milk with a fat content of 38 g/kg, contains approximately 2×10^9 fat globules per milliliter. The range of diameters of the globules (d_{VS}, volume to surface diameter) is about 2 – 5 µm, the mean value is near 3.4 µm.

Homogenization (see Section 7.4) reduces the mean fat globule size to diameters below 1 µm and increases the number of fat globules per unit volume by the third powder of the ratio of the two diameters, e.g.:

$$d_{\mathrm{initial}}/d_{\mathrm{homogenized}} = (3.4/1)^3 = 39.3$$

Thus, the increase in the number of fat globules per milliliter after homogenization will be 40-fold or more, for mean fat globule diameters below 1 µm. According to the temperature of the milk the fat inside the globules is solid, semisolid, or liquid. The state of crystallization of the milk fat inside the globules has considerable impact on cream- and buttermaking properties, it influences the stability of whipped creams as well as their stiffness.

The *milk fat globule membrane (MFGM)* is a true biological membrane of complex composition. Main constituents are polar lipids (phospholipids, cerebrosides, and gangliosides), lipoproteins, and glycoproteins [24]. Practically all of the milk cholesterol (ca. 130 mg per kilogram whole milk) is located in the MFGM. During skimming of milk, some membrane fragments remain in the defatted milk. The cholesterol content of skim milk is about 20 – 30 mg per kilogram skim milk.

Characteristic membrane proteins are, among others the enzyme xanthine oxidase (see Section 3.2.4) and the glycoprotein butyrophilin. The natural MFGM provides emulsion stability and protection against lipolysis of the fat. Homogenization leads to drastic changes in the membrane structure of fat globules. As the total fat area is enlarged, proteins from the bulk aqueous phase are adsorbed to the newly exposed fat surface and form a secondary membrane.

Fat globules can form clusters and produce aggregates, which lead to rapid creaming. A heat sensitive immunoglobulin fraction, IgM, is capable of agglutinating fat globules into clusters.

3.2. Milk Proteins

3.2.1. Major Nitrogen Fractions in Milk [27]

By convention, the total nitrogen content of milk (NT) is divided into two fractions, named according to Rowland [28]: i.e., casein nitrogen (CN) and noncasein nitrogen (NCN). The latter consists of two fractions, the serum protein nitrogen (SPN) and the nonprotein nitrogen (NPN).

The different nitrogen fractions of milk are established as follows:

NCN: = Nitrogen content determined according to Kjeldahl of the filtrate obtained by precipitation of the total casein at pH 4.6,

NPN: = Kjeldahl nitrogen of the filtrate obtained by precipitation of the total "true" proteins with trichloroacetic acid,

SPN: = Noncasein nitrogen minus nonprotein nitrogen (NCN − NPN)

A conversion factor of 6.38 is used to convert the nitrogen content measured into protein content.

The "true protein" content of milk is also defined as (NT − NPN) × 6.38. The value 6.38 assumes that the mean nitrogen content of (isolated) milk protein is 15.7 % which is close to reality, as shown by calculation of the nitrogen contents of milk proteins of known primary structure.

The casein fraction amounts to 75 – 80 % of the total milk protein with an average near 78 %. The serum (whey) protein fraction accounts for 15 – 18 % of the total protein and the NPN contributes to about 5 %.

3.2.2. Nomenclature and Properties of Cow's Milk Proteins [34]

Milk proteins are classified according to their primary structure, as presented in Table 3.

The major *caseins* are α-caseins, β-casein, and κ-casein. γ-Caseins are fragments of β-casein, resulting from a selective cleavage of this protein by plasmin (see Section 3.2.4). The *proteose peptones* 5, 8-slow, and 8-fast, correspond to the N-terminal fragments formed by plasmin catalyzed cleavage of β-casein. Proteose peptone 3, has a different origin, as it is derived from the MFGM. The most abundant whey protein of bovine milk, β-lactoglobulin, is absent

Table 3. Nomenclature, abundance, and properties of cow's milk proteins [34]

Protein species, common name [34]	Abbreviation [34]	Av. concentr. (g/kg milk)	Molecular mass	Genet.variant considered [a]	amino acid residue/mole	S – S bridges mole	perfree SH groups/mole	– PO_4 per mole	Isoionic pH	Glycoprotein yes/no
Caseins and Casein fragments										
αs1-Casein	αs1-CN	11	23614	B-8P	199	0	0	8	4.9	no
αs2-Casein [b]	αs2-CN	3	25230	A-11P	207	1	0	11	5.3	no

MFG Membrane proteins [f]	MFGM	ca. 0.4								yes

[a] Calculated from the respective sequence data of the indicated genetic variant.
[b] This casein forms monomers and randomly disulfide bridged dimers.
[c] Disulfide bridges are also intermolecular and form S-S bonded oligomers of the proteins.
[d] Immunoglobulins are composed of H(heavy)-chains (M_r ca. 55000) and L(light)-chains (M_r ca. 25000). IgG1 and G2 are composed of 2 H-chains and 2 L-chains each. The 2 H-chains are linked via 2 disulfide bridges, 2 further disulfide bridges link each L-chain to a H-chain. IgA is a dimer of 2 H- and 2 L-chains, joined via one J-chain (16500). IgM is a pentamer of IgG and includes a central J-chain.
[e] Iron saturated lactoferrin carries 2 ferric ions per mole.
[f] MFGM Proteins are a heterogeneous group of glyco- and lipoproteins.

in human milk. Human milk contains as major whey proteins α-lactalbumin, lactoferrin, and immunoglobulin.

3.2.3. Caseins [35, 38]

The caseins are synthesized in the mammary gland, stressing their eminent role in the nutrition of the newborn mammal. α-Caseins (α-s_1- and α-s_2-casein) are the predominant casein species in bovine milk (see Table 3), while β-casein is the most abundant casein in bovine, goat's, mare's and human milk. A common feature of all caseins is the presence of one (in κ-casein) to several (α- and β-caseins) phosphoserine residues per mole.

Caseins in cow's milk are present in form of colloidal particles (*micelles*), with spherical diameters in the range of 20 – 400 nm. Micelles separated from milk by ultracentrifugation contain 7 – 8 % of minerals, in form of calcium phosphate and calcium-magnesium citrate complexes. The colloidal calcium phosphate complex of milk has a structure resembling that of hydroxyapatite. The micelles are strongly hydrated and bind about their four-fold weight of water.

This indicates that casein micelles must have a very open, sponge like structure.

Self-association of caseins via interaction of their hydrophobic regions is one of the key elements leading to micelles. Micelles are furthermore kept together by calcium phosphate bridges linking smaller casein aggregates (submicelles) to form larger aggregates (micelles).

Casein micelles lose coherence at low temperature (4 – 10 °C), due to the weakening of the hydrophobic protein-protein interactions. Under these conditions, a fraction of the casein is released into solution ("serum casein"), a process which is reversed if the milk is again warmed up. Micelles resist intense heat treatments such as UHT-heating or retort sterilization to a remarkable extent.

The lower pH limit for stability of the micelle is near pH 5.0. At a pH of 4.6, the total casein has precipitated and can be recovered as insoluble *acid casein*. The precipitated casein can be solubilized by addition of base; dissolution is achieved by raising the pH slowly to 6.8 or higher. This leads to the *caseinates* (see 3.2.3).

Rennet Clotting and Curd Formation [36]. A highly specific proteolytic process is the molecular basis of cheese making. Renneting milk with calf rennet or microbial "rennets", leads to the formation of a curd which is essentially composed of the milk casein (para-casein) and included fat and minerals (→ Cheese, Processed Cheese, and Whey).

3.2.4. Whey Proteins [35, 37, 38]

In contrast to the caseins the whey proteins are soluble proteins. The most abundant whey protein, *β-lactoglobulin* is present as a dimer in both, milk and in sweet whey. The dimer dissociates to monomers at pH < 3.5. In the pH range 3.7 – 6.5, the protein aggregates to form an octamer. This reaction is reversible. In contrast to the heat stable casein, whey proteins are readily denatured by heat treatments above 70 °C. As a result of such heat treatments, denatured whey proteins aggregate, coagulate or, depending on their concentration and environmental conditions such as pH and ionic strength, form protein gels. Although most of the whey proteins participate in such heat induced reactions, the role of β-lactoglobulin is dominant. Upon heating, the protein exposes its reactive thiol group (associated with cysteine [120]). The thiol group acts as a promoter of disulfide exchange and polymerization reactions, particularly at pH $>$ 6.7.

When whey proteins are denatured in milk, visible coagulation or gelling does not occur, as the denatured whey proteins interact with casein micelles to form a colloidal complex (see also Section 7.3.2). The formation of this complex has considerable technological importance in evaporated, shelf stable milks (see Section 9.2), in yogurt production (see Section 9.4), and is also the basis of coprecipitate production (see 3.2.4). While serum protein denaturation favorably influences the stability of evaporated milks and prevents syneresis in yogurt gels, it has a negative impact on the curd forming properties of cheese milks. Whey protein denaturation leads here to an increase in the rennet coagulation time, it lowers curd strength and reduces curd yield.

Table 4. Technologically relevant enzymes in milk [35, 39, 40]

Enzyme	EC classific	Concentration in raw milk, mg/L	Action in milk	Heat stability
Plasmin	3.4.21.7	0.1 – 1	proteolysis of caseins	survives direct UHT
Lipase	3.1.1.3	1 – 2	lipolysis of milk fat	*D* (72 °C) ca. 6 s
Alkaline phosphatase	3.1.3.1	300 – 500 mU/mL	hydrolysis of organic phosphoesters	*D* (72 °C) ca. 5 s
Lactoperoxidase	1.11.1.7	ca. 30	oxidation of thiocyanate	*D* (72 °C) ca. 100 s
Xanthine oxidase	1.2.3.2	ca. 35	conversion of xanthine into uric acid	partly inactivated in pasteurization
Catalase	1.11.1.6		decomposition of peroxide	survives pasteurization
Sulfhydryl oxidase	1.8.	ca. 10	oxidizes thiol groups to disulfides	partly inactivated in pasteurization

The whey protein quantitatively next important to β-lactoglobulin, α-*lactalbumin*, is devoid of a free thiol group while it contains four disulfide bonds which provide considerable structural stability.

α-Lactalbumin is produced in the endoplasmatic reticulum of the mammary gland and its function is to synthesize lactose in combination with the enzyme galactosyltransferase. α-Lactalbumin is found in the milk of all mammals. Native α-lactalbumin carries one calcium ion per mole. Although the protein has a somewhat lower denaturation temperature (60 – 61°C as compared with about 75 °C for β-lactoglobulin), it appears more heat stable as it resists heat-induced precipitation better than other whey proteins.

Milk *serum albumin* originates from blood and is also identical with blood serum albumin of the same species. Remarkable features of this protein are its primary structure stabilized by 17 disulfide bonds and folded into three major domains, as well as its capacity to act as a carrier of long-chain fatty acids.

Milk contains *immunoglobulins* of the *IgG, IgM* and *IgA* type; colostral milk being particularly rich in immunoglobulins. The biological function of immunoglobulins consists in a passive immunization of the calf via ingested colostrum.

From a milk processing point of view, the immunoglobulin fraction of early lactation milks reduces its heat stability; this is the reason why milks from early stages of lactation are excluded from production milks.

Milk Enzymes as Minor Proteins of the Whey Fraction [35]. The number of different endogenous enzymes in milk is very high ($>$ 50) but only some of them are technologically relevant. The most important of these enzymes and their catalytic activities are listed in Table 4. Most of these enzymes are found in whey, only a few of them remain micelle associated (plasmin and to some extent lipase), others are constituents of the MFGM (e.g., xanthine oxidase).

Milk plasmin is a protease derived from the fibrinolytic system of the blood and transferred from blood into the milk. Milk plasmin effects specific cleavage of β-casein to form γ-caseins and proteose peptones (components 5 and 8). Although β-casein is by far the most sensitive plasmin substrate, cleavage of other caseins, such as α-s_2-casein takes place as well. Plasmin induced proteolysis of milk casein may also play a role in cold stored milk. Further proteolysis of the caseins induces bitterness in the milk product via formation of bitter tasting, hydrophobic peptides. Plasmin occurs in freshly drawn milk to a large extent in form of its inactive precursor, *plasminogen*. Plasmin activity increases during storage of the milk by conversion of plasminogen into active plasmin.

Milk lipase (also called lipoprotein lipase), is important in milk processing. If milk is homogenized without prior pasteurization or severely sheared by pumping and other mechanical treatment, the milk fat undergoes rapid lipase induced lipolysis. Standard pasteurization will lead to a sufficient ($>$ 90 %) inactivation of the lipase to prevent lipolytic deterioration.

Lactoperoxidase (LPO), present in a concentration of ca. 30 mg/L in milk, has antibacterial activity through its ability to oxidize thiocyanate ions (SCN^-) into the antibacterial hypothiocyanite ion ($OSCN^-$). As lactoperoxidase is inactivated in the temperature range above 70 °C, its activity can be used to differentiate pasteur-

ized milk (LPO active) from "ultra-pasteurized" (LPO negative) milk (see Section 7.3.2).

Alkaline phosphatase is found after creaming of the raw milk in both, the skim milk phase, and in the cream. Alkaline phosphatase activity is the indicator for milk pasteurization see Section 7.3.2).

3.2.5. Nonprotein Nitrogen (NPN) [41]

About 5 % of the total nitrogen (NT) of bovine milk consist of NPN. In absolute terms NPN amounts to about 25 – 30 mg nitrogen per 100 g of milk. Most of the milk NPN derives from urea, while the minor part of it is composed of different amines, including small amounts of amino acids and oligopeptides.

3.3. Lactose [42]

The lactose content of bulk milk (ca. 48 g/kg) is rather invariable. The milk sugar represents roughly 50 % of the total dry solids of skimmed cow's milk.

Lactose (→ Lactose and Derivatives) is produced in the mammary gland from glucose by phosphorylation and epimerization to UDP-galactose. UDP-galactose is then condensed with another molecule of glucose to 4-*O*-β-D-galactopyranosyl-D-glucopyranose (lactose).

In dry milk, lactose occurs essentially in an amorphous state. As amorphous lactose is hygroscopic, milk powders, stored in a humid atmosphere, increase their water activity (a_w).

An increasing water activity induces partial crystallization of lactose and triggers the onset of Maillard type reactions leading to browning of the powder.

Hydrolysis and Fermentation of Milk Lactose [43]. Enzymatic hydrolysis of lactose by β-galactosidase (lactase) is one of the possibilities to produce lactose-reduced milk and milk products intended for lactose intolerant consumers.

Lactose is the substrate of lactic fermentation by lactic acid bacteria. These metabolize the sugar to lactate. The lactic acid concentration in milks fermented with typical yogurt culture is ca 1 %; corresponding to the fermentation of about 20 % of the initial lactose in milk (see Section 9.4).

3.4. Minerals [11, 42]

The mineral content of bovine milk is compared to that of human and buffalo milk (Table 5). Human milk has a relatively low mineral content in comparison with bovine, goat's, sheep, or buffalo milk. In all milks, potassium is the most abundant mineral, followed by calcium.

The variation in mineral content during the season is relatively moderate; higher than aver-

Table 5. Mineral content of bovine and human milk [11]

Minerals	Cow's	Human	Buffalo
Macrominerals, g/kg whole milk

Tocopherol (vitamin E)	88	520		10

age chloride content may reveal udder disease (mastitis).

The high calcium content (31 mmol/L) is a biological requirement for the newborn mammal to enable build-up of bone mass. The rather limited solubility of the mineral is overcome by the existence of a colloidal complex of calcium with phosphate and citrate ions, in which negatively charged residues of the casein (phosphoserine residues and carboxyl groups) participate. Nearly 70 % of the milk calcium is present in this colloidal state, as well as about 45 % of the total milk phosphate.

Most of the *trace elements* in milk are bound to proteins or associated with MFGM components.

3.5. Vitamins [11, 42]

The role of milk as a source of vitamins is illustrated in Table 6. Riboflavin (vitamin B_2) and cobalamin (vitamin B_{12}) are particularly important, 1 L of milk covering 100 % of the recommended daily intake in these vitamins. The levels of other water-soluble vitamins such as thiamine (vitamin B_1), pyridoxine (vitamin B_6), niacin, and folic acid are much lower and the contribution of milk to the recommended daily intake is modest. The type of feed of the cows influences the milk content in fat-soluble vitamins such as retinol, calciferol, and α-tocopherol. Fat-soluble vitamins are virtually absent in skimmed milk, while the content of skimmed milk in water soluble vitamins is very similar to that of whole milk.

3.6. Contaminants [44]

Bacterial Enzymes and Metabolites. Bacterial proliferation in milk results in the contamination with (released or secreted) bacterial enzymes, of which the proteases and lipases are of critical importance. Both enzymes can seriously reduce shelf life of UHT milks or milk concentrates by development of bitterness and by causing so-called age gelling. The high resistance of bacterial proteases to UHT treatment leads to the gelling of long shelf life milk after a few weeks or months. Gelling is believed to result from partial proteolysis of κ-casein by the bacterial protease and subsequent destabilization of the casein micelle.

Cold storage of raw milk may end with very high viable counts of psychrotrophic bacteria such as *Pseudomonas* species. *Pseudomonas* species produce heat stable, extracellular proteases, even at refrigerated storage conditions. Inactivation of such proteases could be achieved at temperatures between 50 – 60 °C where an autodigestion process reduces the content in active protease [45].

Bacterial or Fungal Toxins. *Aflatoxins* find their way into the feed of dairy cows, e.g., via oilseed cakes. Ingested aflatoxin is metabolized to the likewise toxic hydroxy form *aflatoxin M1* (M stands for milk); aflatoxin M is being excreted in the milk. All aflatoxins are potent carcinogens and induce liver cancer, when ingested by test animals. Surveys carried out in milk and milk products revealed, in most cases, contamination levels in the order of < 0.5 µg/kg milk; the presently proposed tolerance for aflatoxin M1 in milk is 0.5 µg/kg.

Pesticides [44]. Pesticide residues detectable in milk originate from chemical treatment of weeds with herbicides, or by the treatment of skin parasites and insects on farms. Occasional sources of contamination may be oilseed cakes given as supplementary feed. Most countries restrict or forbid the use of *organochlorine pesticides* (e.g., aldrin, dieldrin, hexachlorocyclohexane, or DDT) in the direct neighborhood of dairy farms.

These compounds are not easily metabolized in vivo and, due to their high lipophilicity, accumulated in the fat cells of the adipose tissue. In the dairy cow, the ingested and stored organochlorine pesticides are secreted with the milk fat. Contamination levels of the order of 0.01 mg/kg of milk fat have been established in surveys in several countries.

These contamination levels do not represent any risk of toxic effects.

Organophosphates and carbamates (e.g., dichlorvos, parathion, or malathion) are less persistent and much more biodegradable. For this reason these compounds do not accumulate in the organism to a significant extent. Secretion into milk is therefore much less important than with organochlorine pesticides.

Veterinary Drugs and Hormones. Chemotherapeutics such as *antibiotics* (e.g., penicillins, tetracyclines, chloramphenicols, and streptomycins) and *sulfonamides*, as well as *parasiticides* are applied in the treatment of a wide spectrum of diseases of dairy cows. Udder infections are controlled by direct intra-mammary injection of antibiotics and sulfa drugs. Depending on the nature of the drug, withholding periods of up to 21 days are legally prescribed to protect production milks from contamination with such drugs. The presence of antibiotics creates a number of problems during further processing of the milk: it compromises the maturation of cheeses by inhibition of lactic and propionic acid bacteria, decreases acid and flavor production in fermented milks, and diminishes growth of starter cultures in yogurt, sour milk, or fermented buttermilk production. It cannot be excluded that consumption of some antibiotics via contaminated milk can lead to antibiotic resistance in the consumer. Antibiotics such as penicillins can elicit allergic reactions in sensitive persons.

Polypeptide Hormones. Treatment of dairy cows with recombinant *bovine somatotropin* (BST) is permitted in some countries with the objective to raise the milk output per cow. The hormone is mainly used in the USA, where its application in dairy cattle was approved in 1994. In the European dairy countries the use of this hormone remains banned, mainly for food safety considerations and animal health concerns [46]. The natural, endogenous polypeptide hormone occurs in bovine milk only in ppm concentrations. The natural hormone cannot be distinguished from the virtually identical recombinant hormone.

Heavy Metals. Heavy metal pollution due to industrial and traffic induced air pollution, has led to an increasing concentration of these toxic elements in animal feed and in food for humans.

In the past, most of the *lead* in milk originated from pasture pollution by automobile exhaust gases. The introduction of unleaded gasoline has been a decisive step to reduce this source of pollution. A risk of lead contamination comes from lead containing solder in cans used for evaporated milk.

Mercury contamination of milk is rare and usually the result of carry-over of mercury containing disinfection agents. Normal contents of lead, cadmium, or mercury in milk and milk products are extremely low and their reliable analytical determination needs specialized laboratory techniques.

Radioactive Elements. Fallout from nuclear weapon tests and atmospheric pollution by accidents in nuclear plants can lead to radioactive contamination of milk with radioisotopes, via the ingestion of polluted fodder by the

dairy cow. Radioisotopes resulting from such a nuclear pollution of the geosphere include ^{131}I, ^{134}Cs, ^{137}Cs, ^{90}Sr, and ^{239}Pb. Explosion of the Chernobyl reactor caused the emission of dangerous radioisotopes such as ^{131} I, ^{137}Cs, and ^{132}Te into the atmosphere. Besides extensive contamination of the local land, fallout of these isotopes in northern Europe and other regions caused contamination of milk and other foods with these isotopes.

Nitrate, Nitrite, and Nitrosamines. The endogenous nitrate content of milk varies between 20 µg/100 g and > 1 mg/100 g. Nitrate may be added to cheese milk with the purpose to inhibit gas formation in the maturating cheese, which is induced by the metabolic activity of *Clostridia* species. According to German and Dutch legislation, the addition of up to 15 g potassium nitrate per 100 kilogram of cheese milk is permitted.

In contrast to nitrate, *nitrite* is considered to be a contaminant, normally not present in milk. In raw milk, nitrite may be present in ppm amounts while for *nitrosamines* only traces are tolerable, if any.

4. Physical and Physicochemical Properties of Milk [7, 8, 47]

The physical properties of milk are of greatest importance in its analytical control and in its industrial processing. The most important of these properties are presented in Table 7.

The mean density of skim milk is 1035 kg/m^3, while that of whole milk is about 1030 kg/m^3.

The total solids content of any bulk milk can be approximated from the density and the fat content according to the Fleischmann formula [47]:

$$\mathrm{TS} = 1.2 \times \mathrm{fatcontent} + 266.5\,[(d-1)d]$$

Measuring the *freezing point* of milk it a routine procedure to detect dilution of milk with water or whey. An increase by 0.01 °C corresponds to an increase in the water content by 2 %. Lactic acid fermentation leads to a decrease in the freeing point, as the concentration of osmotically active species is increased (1 mol of lactose yields 4 mol of osmotically active lactate).

The viscosity of milk, at a given temperature, is determined by the viscosity of the outer phase (the milk serum with a viscosity very close to that of water) and the volume fraction occupied by both, casein micelles and fat globules. During concentration of skim milk the viscosity rises as a result of an increasing volume fraction ϕ occupied by the casein micelles and whey proteins. Such an increase in viscosity is higher after denaturation of the whey proteins (in the nonconcentrated milk).

The temperature dependence of milk viscosity at a fat content of 3.7 % is given by the empirical equation [47]:

$$\eta = 1.6 \times 10^{-7} \times \mathrm{e}^{(2741.5/t+273)} + 0.0002$$

The *specific heat* of skimmed milk is slightly higher than that of whole milk, due to the lower water content of a same volume of whole milk. This effect becomes important with creams of increasing fat content; 35 % fat cream has a much smaller heat capacity than whole milk (ca. 3000 Jkg^{-1} K^{-1} in comparison with 3900 Jkg^{-1} K^{-1}.

The *redox potential* of milk is mainly determined by its ascorbic acid (vitamin C) content, by the amount of dissolved oxygen, and by the concentration of reducing SH groups. The value for unheated milk is near 0.3 V. The value decreases for heated milk due to expulsion of oxygen and also due to the destruction of ascorbic acid.

Proliferation of bacteria leads to a strong decrease in the E_0 value, due to oxygen consumption and the activity of reducing enzymes.

The *specific conductivity* of milk is in the order of 4.5 – 5.0 × 10^{-3} S/cm. Milk with markedly higher values of conductivity indicate udder infection, as a result of increased chloride content of milks derived from cows with udder disease. The electrical conductivity of milk decreases with increasing fat content.

The *normal pH* of milk is 6.5 – 6.7. Raw milk with a higher pH than 6.8 can come from mastitic cows, or can be the result of contamination with detergents. A pH < 6.5 indicates beginning acidification; this is also indicated by higher °SH values (> 8 °SH). A direct relation between pH and titratable acidity expressed in °SH, is missing. Heat treatment of raw milk leads to a small

Table 7. Physical and physicochemical properties of bulk milk [7, 8, 47]

	Average	Range	Specifics
Density, kg/m^3			
Whole milk (3.5 % fat)	1030	1029 – 1031	measured at 20 °C
Skim milk	1035	1034 – 1037	
Freezing point, °C		− 0.51 to − 0.55	each increase by 0.01 °C indicates addition of 2 % water
Dynamic viscosity, mPa · s			
Whole milk (3.5 % fat)		1.4 – 1.7	measured at 20 °C
Skim milk		1.2 – 1.5	
Condensed milk (10 % fat)	ca. 25		
Cream (15 % fat)	ca. 10		
Electrical conductivity, mS/cm			measured at 25 °C
Whole milk	5	4.0 – 5.5	increased Na^+ and Cl^- concentrations (subclinical mastitis) lead to higher conductivities
Specific heat, J kg^{-1} K^{-1}			
Skim milk	4000	3980 – 4020	valid for temperature range 0 – 70 °C
Whole milk	3900		fat content 3 – 4.3 %
Thermal conductivity, W m^{-1} K^{-1} (at 20 °C)			
Skim milk		0.54 – 0.64	
Whole milk		0.52 – 0.6	
pH			
Normal whole milk		6.5 – 6.7	
Mastitic milk		$\geq$ 6.8	
Sour milks		4.6 – 4.9	
Yogurts		4.0 – 4.3	
Titratable acidity, °SH			
Fresh whole milk		6 – 8	titratable acidity mainly due to phosphate
Yogurt		38 – 52	44 SH correspond to a lactic acid content of 1 %
Redox potential, V			
Raw whole milk		0.25 – 0.35	main factors are ascorbic acid content, dissolved oxygen and reactive SH-groups
Past. whole milk			
Sterilized milk	− 0.05		intensive heat treatment destroys ascorbic acid, removes oxygen.
Yogurt	− 0.15		proliferation of bacteria reduces oxygen

pH increase (by release of CO_2) and, at higher heat loads, to a pH decrease (acid formation via Maillard reaction, formation of tricalcium phosphates and release of H^+ ions). Concentration by evaporation leads to a lowering of the pH.

Titratable acidity is measured by titration of milk to pH 8.3 with 0.25 mol/L sodium hydroxide solution. The Soxhlet-Henkel number (°SH) equals the milliliters of titrant needed to titrate milk to the end point of the indicator. 1 °SH corresponds to 0.0225 % lactic acid.

Color and Lightness. The optical appearance of milk, expressed in the CIE-LAB color system, is dominated by its lightness. The Hunter L-value measures the relation between reflected and absorbed light without consideration of a specific wavelength. Whole milk has a higher L-value (range 80 – 84, depending on fat content and heat treatment) than skim milk, due to the light scattering contribution of the fat globules. The value for skim milk depends on the heat treatment and ranges from ca. 75 to 78.

Heat denaturation of whey proteins leading to their aggregation, causes a small increase in lightness.

Severe heat treatments followed by advanced Maillard reaction reduce the lightness via formation of brown pigments.

5. Microbiology of Milk [49 – 51, 143]

Milk is a good growth medium for most microorganisms, desirable ones such as lactic bacteria used in the production of fermented milks, as well as undesirable ones (spoilage bacteria and pathogenic bacteria). Although milk contains usually < 1000 viable bacteria per milliliter on leaving the udder ducts, the temperature of the freshly drawn milk (37 °C), favors their propagation during the milking process. Contamination by exogenous microorganisms occurring during the milking procedure and during storage, adds to further increase in the total viable count of raw milk.

While *psychrotrophic bacteria* constitute an insignificant proportion of the milk flora in freshly drawn raw milk, these organisms may proliferate in milk during refrigerated storage. This is typical for bacteria of the genus *Pseudomonas*, *Flavobacterium*, and *Alcaligenes* species. Many of these bacteria produce extracellular enzymes such as proteases, lipases, and others, implicated in flavor defects or stability problems encountered with UHT milks.

Enterobacteriacea such as *Escherichia*, *Enterobacter*, *Citrobacter*, *Klebsiella*, *Proteus*, and *Serratia* species are major representatives of the spoilage flora of milk. High levels of *Enterobacteriacea* are occasionally associated with odor and flavor deterioration, slime formation or color development.

High viable counts (> 100 colony forming units, i.e., cfu/mL) of *coliform organisms* indicate serious contamination of the raw milk due to handling or unclean equipment.

Among the *spore forming bacteria*, *Bacillus* and *Clostridium* species produce heat resistant spores surviving pasteurizing treatments. *Bacillus cereus*, capable of growing at refrigeration temperatures, presents a particular problem in fresh or pasteurized milk products.

Clostridia such as *Clostridium tyrobutyricum* and others are a problem in hard cheeses, as the growth of this organism leads to production of gas and late cheese blowing.

Lactic bacteria of the genus *Streptococcus, Lactobacillus* and *Leuconostoc*, although suppressed in their growth at low temperature, are a problem in insufficiently refrigerated milk as they cause rapid souring.

The *total viable count,* expressed in colony forming units per milliliter of raw milk varies between several ten thousands and a million at the moment of the delivery to the dairy. Depending on the country, payment penalties due to insufficient bacteriological quality are applied at bacterial loads of $> 10^5$ cfu/mL [143].

Pathogenic bacteria [51] in milk originate either from the milk of infected cows or they are introduced by contamination of milking equipment and handling of milk or processing equipment. The most critical pathogens presenting a potential health hazard in raw milk are: *Mycobacterium tuberculosis*, *Brucella abortus*, *Coxiella burneti*, *Staphylococcus aureus*, *Streptococcus agalacticae*, *Salmonella* species, *Campylobacter*, and *Listeria monocytogenes.* The pathogenic flora is efficiently destroyed by pasteurization (see Section 7.3). Rigorous veterinary control of herds has limited the risk of infection of milk with *M. tuberculosis,* in developed countries.

Yeast and molds are of less importance in the spoilage of milk or cream, as they do not compete vigorously with the bacterial flora except in milk products with a low pH (such as fermented milks). They take also some importance in ripening of cheese where they may contaminate the surface of the cheese.

Milk *somatic cell count* (number of leukocytes) is used as a criterion of milk quality, particularly for the mastitis incidence in a dairy herd. The number of somatic cells in milk from healthy cows ranges between 10^5 and ca. 3×10^5 cells/mL. The rejection limit for milk with too high somatic cell counts is fixed at levels of $> 4 \times 10^5$ to $> 8 \times 10^5$ cells/mL, depending on the country [143].

Table 8. Milk as an essential nutrients source [52]

Nutrient	RDI [1] for woman >20 a	in 100 g milk (3.5 % fat)	500 g milk equiv. % RDI * [52]

* RDI = recommended daily intake.

6. Nutritional Value of Milk [10, 11, 52, 53]

6.1. Milk as a Nutrient Source for Humans

Milk being the exclusive source of nutrients of all newborn mammals, has a sufficient and balanced content in essential nutrients required for the growing young mammal. After the weaning period, milk consumption makes up for a more or less big fraction of the total nutrient intake of a mammal, including humans. The adequacy of cow's milk to cover human nutritional needs is therefore a function of age. Cow's milk is not the adequate substitute of mother's milk for the human infant. An adaptation in several respects is necessary to produce a valid infant formula based on cow's milk (see Section 9.3.6).

For the growing child and for adults, milk and milk products remain a major source of essential nutrients (see Table 8).

Quality of Milk Protein [53 – 55]. Cow's milk protein is rich in essential amino acids (Table 9). Intensive heat processing of milk such as in the manufacture of evaporated milks or drying reduces the bioavailability of some essential amino acids of the milk protein. Lysine is particularly vulnerable as it undergoes a condensation reaction with lactose to form a nutritionally unavailable amino-1-desoxy derivative (Section 7.3.2.3). Other essential amino acids such as tryptophan, cysteine/cystine and methionine may also suffer damage by extensive heat processing or by drying of milk.

6.2. Health Aspects of Milk Consumption [10, 56]

Milk Fat [57, 58]. Milk fat is a good energy source due to its content in short- and middle-chain fatty acids, which are rapidly metabolized. Consumption of milk fat has, however been associated with development of arteriosclerosis in humans. The abundance of saturated fatty acids such as lauric acid (C_{12}), myristic acid (C_{14}), and palmitic acid (C_{16}) in milk fat is being considered the cause of its artherogenic effect. Whole milk, when added to a diet, was not found to raise total plasma cholesterol in humans, while the replacement of unsaturated vegetable fat by milk fat in test diets did so. This suggested that artherogenicity of milk fat may be little or not expressed when the intake is in form of milk, possibly due to "anti-cholesterogenic factors", of yet unknown nature.

Unsaturated fatty acid with trans configuration of the double bond physically resemble saturated fatty acids and saturated fat when in-

Table 9. Amino acid composition of the milk protein [53]

Amino acid, g/100 g protein	Total milk protein	Cow's milk whey protein	Total casein	Human mature milk
Aspartic acid	7.32	9.87	6.46	9.48

corporated into triglycerides. Their assimilation leads to an increase in low density lipoprotein (LDL) cholesterol, whereas the high density lipoprotein (HDL) cholesterol is being decreased. Their consumption by hypercholesterolemic patients is therefore disadvised. Milk fat contains on average ca. 3 % of its total fatty acids in the trans form. The origin of the trans isomers is in the cow's rumen where unsaturated fatty acids are biohydrogenated, and subsequently desaturated, a reaction leading to *cis – trans* isomerization. In comparison to milk fat, margarine and other hydrogenated vegetable fats contain, following their hardening by catalytic hydrogenation, rather high concentrations of trans isomers [58].

Milk fat includes about 300 mg of cholesterol per 100 g fat. Although dietary cholesterol has little impact on the serum cholesterol levels of normal individuals, oxidized forms of cholesterol (oxysterols) generated from milk cholesterol during processing or storage, have been shown to be artherogenic in animal studies.

Lactose [43, 59]. Lactose intolerance results from intestinal malabsorption of the milk sugar and causes increased osmotic lumen pressure, abdominal pain, diarrhea and other symptoms. The intolerance is due to a deficiency in the mucosal enzyme β-galactosidase (lactase). Such a deficiency is very frequent in the black population of the USA. In Asian and Latin American more than 50 % of the population suffer from lactose intolerance. In European countries, the frequency of lactose intolerance is low but it a decrease in lactose tolerance occurs with progressing age.

However, many milk intolerant individuals tolerate fermented milks. This is probably due to the activity of ingested bacterial lactases coming from the starter organisms of fermented milk products. Aseptic addition of microbial lactase to pasteurized or UHT-sterilized milk, is a technological approach to reduce the lactose content of milk for lactose intolerant consumers. Such milks are on the European and American market since a few years.

Milk Protein. Milk protein consumption causes cow's milk allergy in 2 – 5 % of newborns [60 – 62]. Sensitization to cow's milk proteins occurs during early feeding the infant with milk formulas and other milk based products. It is likely to occur also when even minor concentrations of cow's milk proteins have found their way via blood circulation, into the breast milk of lactating mothers.

A hereditary disposition for cow's milk allergy has been clearly established. Cow's milk allergy has a transient character, as shown by

its much lower incidence in the adult population. The typical symptoms of cow's milk allergy include skin affections, intestinal affections such as colic, and respiratory symptoms like asthma. Formulas based on enzyme hydrolyzed milk protein have been found in many cases effective in dietary management of cow's milk allergic patients [62].

Milk protein, particularly the casein micelle, appears to play a positive role in *dental protection* as suggested by caries reducing effects of certain cheeses and lactose free milk protein.

Milk protein has a buffering effect and neutralizes, to some extent, acids generated by dental plaque bacteria. It also favors the mineralization of damaged enamel by providing high oral concentrations of soluble calcium. The protective effect of cheese may be related to both, its calcium providing or to the observed stimulation of saliva flow during cheese consumption [64].

Milk Calcium [67]. Milk is an ideal source of calcium and phosphorus for the build up of the skeletal mass of the young individual. Milk and dairy products are likewise a main calcium source in adult and in aging individuals.

7. Dairy Technology

Dairy technology is applied in the processing of raw milk to consumer milk and milk products. Technological processing of milk must guarantee its good hygienic quality and complete safety of the all milk products. It must provide dairy products which have attractive taste quality and texture properties and their full nutritional value.

7.1. Milk Production and Transport [1, 4, 14]

Milking. Today, *manual milking* is restricted to farms with a limited number of dairy cows. With larger herds, *mechanical milking* is performed with the aid of milking machines. The milk is extracted from the teat and udder by a pulsating vacuum in rubber-lined teat cups, fitted around the four teats.

The pulsator ensures physiologically adequate stimulation of milk secretion in the mammary gland by alternating application of vacuum (about 0.5 bar) and atmospheric pressure on the teat cups. The milk then flows through pipelines in a refrigerated storage tank. To avoid propagation of bacteria in the freshly drawn milk, cooling should be as rapid as possible, followed by cooled storage at temperatures ≤ 6 °C. For prolonged storage in cooled tanks, slow agitation is required to prevent the cream from rising.

Cows are usually milked twice a day. A typical daily milk yield per cow is about 20 kg, a mean annual milk production per cow ranges between 5 000 and 7 000 kg; the mean lactation period being about 300 days a year.

Milk Collection and Transport. Time laps between milking and milk collection and its transport to the dairy have become longer due to the growing size of dairy processing plants, collecting milk from a wide area. Mean transport times have also increased accordingly. Cooled storage at the dairy farm or in a collection center usually lasts 24 to 48 h before the milk is further processed in the dairy. In such a case a storage temperature below 6 °C is critical to reduce the growth of mesophilic and thermophilic bacteria. Transport of larger volumes of collected milk takes place in specially devised road tankers equipped with insulated milk tanks of 10 000 and more liters in size. The tankers may be equipped with cooling units to maintain low temperatures during longer transport in hot seasons.

Milk collected in alpine regions may be transported via milk pipelines made of polyethylene or poly(vinyl chloride) to local dairies located in the valleys.

Milk Reception in the Dairy. Control measures carried out upon milk reception in the dairy include the following:

Determination of specific gravity or the freezing point (see Chap. 4) to detect adulteration, e.g., by dilution with water; testing for the absence of antibiotics; rapid assessment of the bacteriological quality (methylene blue reduction test); and qualitative assessment of somatic cells by the so-called Schalm test. In addition to these parameters, the lactose, total protein, and fat contents are regularly monitored by automated infrared milk analysis.

Quality Control. Depending on the country, different criteria are included to determine the quality grade of milk of a particular supplier. These criteria include both hygienic and composition data. Among the hygienic parameters the total viable count and the somatic cell count, are the most important ones (see Chap. 5). Compositional criteria are the total protein content, the fat content, the lactose, and the total solids content.

7.2. Pretreatment in Dairies

Clarification. [4, 14]. Solid particles such as dirt particles, insects, or udder cells are removed from the milk by filtration or centrifugation, using continuous disk centrifuges rotating at 5000 – 6000 rpm with a flow of 10 – 30 m^3/h. The separated sludge accounts for less than 0.1 vol % of the treated milk.

Bactofugation and Bactofiltration. *Bactofugation* is a centrifugation process designed to remove microorganisms such as yeast, spores, and bacteria from milk. The process was introduced in the 1960s to improve the quality of cheese milk and the keeping properties of consumer milks. The most desired effect achieved with a bactofuge is the reduction in the spore content of production milks, as pasteurization does not inactivate bacterial spores and UHT-heating damages the curd forming properties of the milk. Optimum temperature for bacteria separation in a bactofuge is 60 – 70 °C; depending on the density difference between the milk and the microorganisms, a reduction of 1 to 2 orders of magnitude in their number can be achieved.

The *Bactotherm process* by Alfa-Laval, Sweden, uses a combination of bactofugation and UHT-heating (to treat the bacteria enriched bactofugate) and remix it, after heat sterilization, with the debacterized milk.

A more recent nonthermal process to reduce the bacteria and spores content of raw milk, is the *Bactocatch process* by Tetrapak, Sweden. The process is based on a cross-flow microfiltration of skim milk on inorganic membranes with a pore size of 1.4 µm. This microfiltration process can only process skim milk, thus fat separation has to precede and the cream must be separately heat treated. The aluminum oxide membrane is capable of reducing the bacterial population by three to six orders of magnitude, depending on the type of germ. Late cheese blowing does no more occur when cheese milks have been processed with this equipment [68].

Separation and Fat Standardization [4, 12 – 14]. The density difference between milk fat and skim milk is sufficient to allow efficient separation of milk fat in the form of cream. The reduced viscosity of the milk at 50 – 60 °C gives a sharper separation in the cream separator.

Continuously operating disk centrifuges as shown in Figure 1, are used in the industry.

Figure 1. Continuous hermetic disk centrifuge for cream separation (reproduced from TetraPak Dairy Processing Handbook [4] with permission)
a) Disk stack; b) Lock ring; c) Counter-pressure valve; d) Bowl body; e) Distributor; f) Hollow bowl spindle

The whole milk is introduced into the separator via vertically aligned holes in the disks. Under the influence of the centrifugal force, the fat droplets settle inward the channels, close to the axis of rotation and the cream moves further along to an axial outlet. The skim milk moves outwards to the space outside the disk stack to a concentric skim milk outlet. The cream fraction usually represents about 10 % of the total throughput, accordingly a cream with 40 %

fat results from a milk having a fat content of 4 %. Depending on the desired fat content of the cream, the throttling valves in the cream and skim milk outlets are adjusted.

Fat standardization of production milks (for milk products of any kind) but also to some extent for consumer milks, is current practice in the dairy industry. To adjust the varying fat content of incoming milk to a specified fixed value, milk fat has to be added or removed. This adjustment can be done batchwise by mixing the appropriate volumes of skim milk and cream to achieve the desired fat content. In large dairies the standardization is often done automatically and in-line by means of continuous density monitoring of the fat content in the cream stream and computer controlled regulation of the flow of the streams of both skim milk and cream.

Degassing. Milk contains about 6 vol % air after milking. The amount of included air may increase to about 10 % due to handling and transportation. This leads to problems in measuring density and other physical parameters in the dairy. The same air will adversely affect the functioning of heat exchangers, centrifuges, and other equipment. Degassing of milk is achieved by either increasing its temperature and/or reducing the pressure. In most cases, deaeration is achieved in a vacuum tank in which the pressure is reduced to such an extent that the temperature of the milk drops by about 8 °C. This causes the evaporation of water, air and other volatile components are entrained.

Degassing is particularly important for good taste quality of butter. During UHT-heating, volatile substances are also removed together with water vapor in an expansion vessel (steam injection process). The vacuum expansion following the heat treatment in an UHT plant eliminates certain volatile components such as mercaptans from the milk.

7.3. Thermal Treatment

7.3.1. Thermal Processes [4, 12 – 14, 69]

(see also → Foods, 2. Food Technology, Chap. 4; → Heat Exchange)

Of all the steps used in milk processing, thermal treatment is by far the most important. The aims of heat treatment are the extension of shelf life, achievement of bacteriological and hygienic safety, the improvement of technological and functional properties of milk constituents and the development of desirable flavor properties. Thermal treatment destroys microorganisms and inactivates enzymes. It causes denaturation of whey proteins and accelerates chemical reactions such as the activation of SH groups; isomerization of lactose; Maillard reactions involving lactose and the ϵ-amino group of lysine; and others. The multiple benefits of heat treatment must be balanced with its negative impact on some heat sensitive nutrients in milk, such as certain vitamins. Heat treatments must therefore be carefully optimized and the best compromise found between safety and shelf life demands on the one hand, and minimum damage to nutritional quality on the other.

Thermization is a treatment of raw milk at temperatures below pasteurization temperature, aimed at reducing the number of bacteria during a cold storage of the milk prior to its final processing. Temperatures used for thermization range from 57 to 68 °C, and holding times are in the range of 10 – 15 s. Thermized milk must remain phosphatase positive.

Pasteurization [70] (→ Foods, 2. Food Technology, Section 4.1) has the aim to destroy all pathogenic microorganisms in milk, notably *Mycobacterium tuberculosis* and other pathogens such as *Brucella species, Salmonella* or *Escherichia coli* bacteria. While reducing the number of viable vegetative bacteria by several orders of magnitude, pasteurization does not reduce the content in viable spores. In view of the low intensity of a pasteurizing heat treatment, the nutritional quality of pasteurized milks is virtually unimpaired.

Depending on the equipment used in a dairy plant, different pasteurization conditions are applied.

Batch or *holding pasteurization*, the oldest method of pasteurization, is performed at 62 – 65 °C for 30 min. This process has been largely replaced by the continuous *high-temperature short-time (HTST)* procedure, where the milk is rapidly (within a few seconds) heated to temperatures ranging from 71 to 74 °C and held for

15 to 20 s at this temperature. Typical pasteurization conditions in European dairies are 72 °C and 15 – 20 s. The alkaline phosphatase activity of the heated milk is used to check pasteurization efficiency; adequate pasteurization results in a negative phosphatase test (see Section 7.3.2).

HTST pasteurization is performed with plate heat exchangers transferring the heat across the metal wall from the heating medium (hot water) to the product (milk) or, in the regeneration section, from the outflowing heated milk to the incoming, cool milk. Between the heating and the cooling section, a holding tube is inserted to provide the necessary holding time of the milk at the pasteurization temperature. The heated milk flows through the cooling section where it is cooled with ice water or brine.

For *cream* pasteurization a more intense heat treatment is required to achieve the same bacteriological safety as with pasteurized milk [71]. Pasteurization temperatures of 75 – 80 °C and holding times up to 30 s are adequate. To increase the shelf life of pasteurized cream, thermal treatments (85 – 90 °C and 10 – 20 s) are applied to reduce the number of more thermoresistant bacteria such as Streptococci, Micrococci, and Bacilli. This type of thermal treatment is also called high heating.

The expression *ultra pasteurization* is used to designate very short heat treatments (typically about < 2 s at 138 °C), mainly applied in the United States and Canada to produce consumer milk with an extended (refrigerated) shelf life (ESL milk), about twice that of standard pasteurized milk [33].

Ultrahigh Temperature (UHT) Heating (see also → Foods, 2. Food Technology).

The term UHT heating applies to a continuous process leading to a sterile product. The characteristic temperature range for UHT heating is 135 – 150 °C with holding times of a few seconds. The aim of an UHT process is to achieve a sterile product storable at ambient temperature. The heat treatment must destroy all microorganisms (spores of heat resistant bacilli included) and the product must be packaged aseptically into sterile, hermetically sealed packages. This is achieved in aseptic filling machines such as the Tetra Pak fillers.

UHT heating is performed according to a direct or an indirect process.

Direct UHT Process. In the direct heating process, the product is brought into contact with steam under pressure. The fast condensation of the injected steam heats up the product via transfer of the heat of vaporization of the steam. A consequence of this mixing of steam and milk is the dilution of the milk (by about 10 % or more) by the steam, which needs to be corrected at a later stage in the process.

Two main variants of direct heating plants exist: in the *injection system*, pressured steam is injected into the milk stream in a mixing chamber. An example of an injection plant ("uperization" plant) is shown in Figure 2. While preheating of the milk to the preheating temperature (typically 80 °C) takes a fraction of a minute, the heating time to the sterilization temperature (148 – 150 °C) is extremely short, in the order of a second. The milk is kept under adequate pressure in the holding tube by a restriction valve inserted between holding tube and the expansion vessel. This maintenance of pressure guarantees the appropriate holding temperature during the short holding time of 2 – 4 s. Once the heated milk has passed this valve and reached the expansion chamber, it boils and, at the same time rapidly cools down to near preheating temperature (actually 1 – 2 °C above the preheating temperature, see below). The cooled product is pumped through the homogenizer using an aseptically designed pump. A homogenization step after direct UHT heating by steam injection is required to disperse aggregates formed during the heat treatment. From the homogenizer the product passes through the regeneration section for further cooling and is pumped to an aseptic filling machine.

In the other version called *infusion system*, the milk is sprayed into a chamber filled with steam at the appropriate sterilization temperature. As the milk falls through the chamber, it condenses steam and equilibrates with the steam temperature.

In both variants of the direct UHT process, adequate removal of water during the vacuum expansion step is required, to correct for the dilution caused by the injected, condensed steam. This is achieved by evaporating water from the expansion vessel by adjustment of the temperature to ca. 2 °C above the preheating temperature at which the milk had entered the mixing chamber. The vacuum expansion allows, at the

same time, to strip off undesirable volatile components from the milk.

Indirect UHT Process. Depending on the type of equipment, indirect UHT plants operate either with plate heat exchangers or with tubular heat exchangers. The common feature of all indirect plants is that the heated product does not get into contact with the heating medium (steam), but the two phases are separated by a thin (stainless steel) wall having a very high heat transfer capacity.

Plate heat exchangers present the highest possible heat exchange area on limited space. However for UHT processes, the plates must withstand higher temperatures and resist higher internal pressures. The plate exchanger systems are relatively prone to deposit formation and fouling.

Tubular heat exchangers are better suited to withstand high pressures than plate heat exchangers. Thus tubular exchangers are able to hold more easily the homogenization pressure (15 – 20 MPa).

Indirect UHT plants for UHT milk production often have a nonaseptic homogenization step in the septic part of the plant and end with an aseptic homogenization downstream of the UHT heater. In the case of milk, this second, aseptic homogenization may not be strictly required, as is the case with a direct heating process. Indirect UHT plants have the advantage of a better energy economy, their major disadvantage is fouling of the heat exchanger surfaces, resulting form deposits of heat denatured protein and minerals. Preheating the milk to 90 °C with a holding period of 1 – 2 min causes denaturation of the whey proteins and reduces subsequent deposit formation in the UHT section. A comparison of the time – temperature profiles of direct versus indirect UHT heating process reveals that the indirect process results in a higher

total heat load, due to the relatively long heating time [72].

Retort Sterilization in the Package. Sterilization in the package using an autoclave (or steam retort) is the oldest industrial sterilization technique. The product is being sterilized in its final package such as a metal can, a glass bottle, or a heat-stable plastic (e.g., polyethylene) container. The heat treatment is carried out in a sterilization chamber filled either with saturated steam or hot water under pressure. In batch autoclaves, the product in the package is accommodated in rotating baskets keeping the content of the cans, flasks, or other packages in a constant motion to promote uniform heat treatment of the whole product volume. In the case of a semisolid or solid product, the "cold spot" of the product defines the minimum heating conditions. Time – temperature profiles for retort sterilization of milk products are: 115 – 125 °C (product temperature) for about 10 min. In-package retorting is practiced for the production of evaporated milks, coffee creams, whipping creams, or milk based desserts.

For large industrial productions, continuously operating retorts are used, particularly for the manufacture of canned milk or milk in bottle sterilized milk.

Combined Sterilization Processes. Sterilization in the package is technically much simpler than UHT sterilization followed by aseptic filling. As UHT sterilization is much less product damaging than retorting, it can be an advantage to combine UHT sterilization with a short "post-sterilization" in a retort. Due to the high sterilizing effect of the UHT treatment, the post-sterilizing process operates with a much lower heat load than in normal in-can sterilization; its main task being limited to destroy microorganisms recontaminating the milk during nonaseptic filling.

In retort processes, the total lethal heat load is expressed by the F_0 *value*, a multiple of the sterilizing effect achieved by 1 min holding at a product temperature of 250 °F (121.1 °C) (→ Foods, 2. Food Technology, Section 4.2.1). For a complete retort sterilization process, the F_0 value must be extracted from the temperature – time profile of the operation (including heating and cooling sections). F_0 values between 5 and 7 are mostly applied for retorted milks and evaporated milks.

7.3.2. Effects of Heat on Milk [12, 13, 72, 73]

7.3.2.1. Effect on Microorganisms

The primary goal of heating milk and milk products is to guarantee their microbiological safety and to obtain a sufficient shelf life. This is achieved by a sufficient thermal reduction of viable bacteria and other microorganisms, or by their complete destruction. The inactivation of microorganisms follows a first order process:

$$-\ln(C_t/C_0) = k \cdot t$$

In this equation C_0 is the initial, C_t the final (after heat treatment) concentration of viable microorganisms, k is the temperature dependent death rate constant (expressed in s^{-1} or min^{-1}) and t the heating time, expressed in min. Transformation into

$$\log(C_0/C_t) = (k/2.3) \cdot t$$

leads to a definition of the *decimal reduction time* (D), which expresses the time (in s or min) at a particular temperature to reduce C_0 by a factor of ten. When the ratio of viable counts prior and after the heat treatment $C_0/C_t = 10$; as log 10 = 1, the time to achieve a tenfold (one log) reduction in the initial number of viable bacteria at the temperature ν, is D_ν.

The dependence of the D value on the temperature, for a given microorganism, is described by:

$$z = (v_1 - v_2)/(\log D_1 - \log D_2)$$

Accordingly, the z *value* indicates the temperature increase in °C required, to reduce the D_ν value by a factor of ten (→ Foods, 2. Food Technology, Section 4.2.1).

Thermal death data on bacteria and bacterial spores in milk are shown in Table 10. Time – temperature combinations of heat leading to comparable inactivation of mesophilic or thermophilic spores are apparent from Figure 3.

Figure 3. Effects of heat treatment on milk components (reproduced from [12] with permission)

7.3.2.2. Inactivation of Milk Enzymes [35, 39, 40, 70]

There are considerable differences in the heat sensitivity of important milk enzymes (see Section 3.2.4 and Table 4). Milk lipase and alkaline phosphatase are among the most heat labile enzymes and inactivated to a large extent during milk pasteurization. Other milk enzymes such as catalase, peroxidase, or acid phosphatase are much more resistant and survive pasteurization.

Milk *lipase* is sufficiently inactivated at an early stage of milk processing by standard milk pasteurization, to avoid lipolytic enzyme action during further processing (particularly homogenization). Homogenization greatly enhances the action of lipase on milk fat. Therefore, raw whole milk must never be homogenized without being pasteurized before. Pasteurization is not sufficient to destroy lipase activity from bacterial origins such as the lipases of *Pseudomonas* species and other, mainly psychrotrophic microorganisms (Fig. 3). High numbers of viable psychrotrophs may therefore lead to development of rancidity in UHT milks during their shelf life.

Alkaline phosphatase is inactivated to a high extent during standard milk pasteurization. The

p-nitrophenol method for the determination of residual phosphatase activity can easily detect inadequate pasteurization conditions or recontamination with small volumes of unpasteurized milk [76].

Table 10. Thermal death data on bacteria and spores in milk [69, 70, 73, 74]

Microorganism	*D*-value, s	*z*-value, °C
Endogenous milk flora		
Endog. mesophilic milk flora	9 – 12 (121 °C)	10 – 11
Endog. thermophilic milk flora	23 – 26 (121 °C)	10 – 11
Spores suspensions from:		
Bacillus stearothermophilus	180 (121 °C)	9.4
Bacillus subtilis	20 (121 °C)	6.7
Bacillus cereus	4 (121 °C)	36
Bacillus licheniformis	11 (121 °C)	8
Clostridium sporogenes	4 (121 °C)	11
Pathogenic vegetative germs:		
Mycobacterium tuberculosis	(60 – 70 °C) *	ca. 6
Salmonella enteriditis	12 – 31 (60 °C)	3.3
Listeria monocytogenes	35 – 72 (63 °C)	ca. 5

* Inactivation range of *M. tuberculosis*, no exact *D*-value available

While the *D* value of alkaline phosphatase at 70 °C is near 20 s, that of *lactoperoxidase* is >100 s; this explains that pasteurization has only a small effect on the activity of the latter enzyme. This provides a possibility to differentiate between pasteurized and UHT heated milk, as in the latter, the peroxidase is likewise inactivated. "Overpasteurization" can also lead to a negative peroxidase test.

Milk *plasmin* shows extreme heat resistance, active plasmin is found even in UHT heated milks. The residual plasmin activity in long shelf life milks is held responsible to some extent for taste deterioration (development of bitter taste) and gel formation.

Enzymes from the psychrotrophic microflora such as proteases from *Pseudomonas species* are equally highly heat resistant and limit the keeping quality of UHT milks by proteolysis and age gelling.

7.3.2.3. Heat-Induced Destruction of Nutrients [10, 12, 13, 69]

Vitamins. Losses in both water-soluble and fat-soluble vitamins are negligibly small in standard milk pasteurization. During UHT sterilization, small losses in thiamine, pyridoxine, folic acid, and vitamin B_{12} occur. Thus, losses in thiamine resulting from UHT sterilization range between 1 – 3 % of the initial content (Fig. 3). The oxidized form of vitamin C is destroyed during UHT heating of milk. Oxygen removal from milk to <1 ppm considerably reduces losses in vitamin C during UHT treatment. Losses in heat labile vitamins are much higher in retort sterilization of milk; e.g., for vitamin C loss may exceed 90 %, while for pyridoxine and folic acid, destruction amounts to about 50 % and for thiamine to about 30 %.

Damage to Proteins [77, 78]. As a result of intense heat treatment, several essential amino acids undergo irreversible chemical modifications which, if a significant fraction of the particular amino acid is involved, lead to a reduction in the nutritional value of the milk protein.

The ϵ-amino group of lysine undergoes a condensation reaction with lactose, when milk is heated, evaporated or dried. During the first and reversible stage of the *early Maillard reaction*, the ϵ-amino group condenses with a reducing aldehyde group of the lactose to form the protein bound Schiff base ϵ-lactosyllysine. The Schiff base then rearranges into ϵ-deoxylactulosyllysine. The latter represents an irreversibly blocked and nutritionally unavailable form of protein bound lysine.

In the further progress of *advanced Maillard reactions*, a variety of reactive decomposition products are formed. Among them, *5-hydroxymethylfurfural,* is a good indicator for progressing Maillard reaction in milk and milk products. Reactive intermediates of advanced Maillard reaction condense to form colored polymers (melanoidines). A great number of heterocyclic compounds with pronounced flavor characteristics are produced in the late stages of advanced Maillard reaction. These include *N*-, *S*-, and *O*-heterocyclic structures. The characteristic caramel aromas of severely heated milks are due to *O*-heterocyclic enolones [77].

Analytical determination of "blocked" lysine is based on the release of *furosine* (ϵ-*N*-(furoylmethyl)-L-lysine), and pyridosine from protein bound ϵ-deoxylactosyllysine, during total acid hydrolysis of the protein. Furosine, produced in about 40 % yield on lactosylated lysine, is determined by chromatographic procedures and allows calculation of the amount of blocked lysine in modified protein. UHT-sterilized milks show furosine contents in the range of 20 – 100

Table 11. Indicators for heat treatment in liquid milks [76, 79, 80]

	Lactulose, mg/L		Furosine, mg/L		Undenaturated β-lactoglobulin, mg/L	
Type of milk processing	Typical	Range	Typical	Range	Typical	Range
Raw Milk	0	0	0	0 – 5	3500	3000 – 3800
Pasteurization	5	0 – 10	6	2 – 10	2800	2600 – 3000
Draft EU Directive 92/46 [76]		non detectable				>2600
UHT						
Direct UHT-process	150	100 – 300	20	10 – 40	600	300 – 1000
Indirect UHT-process	300	200 – 1000	40	20 – 90	150	100 – 500
Draft EU Directive 92/46		>100				>50
Sterilization	1000	600 – 1200	100	75 – 150	0	0
Draft EU Directive 92/46 [76]		>600				< 50

mg/L. Retort sterilized milks give furosine contents of 100 mg/L and higher. A furosine content of 100 mg/L corresponds to the blockage of ca. 10 % of the total protein-bound lysine. Losses of >10 % of the total lysine significantly reduce the biological value of the protein.

The sulfur-containing amino acids *methionine* and *cysteine* can be partially desulfurated during intense heat treatments. Removal of sulfur from cysteine or methionine gives rise to volatile mercapto derivatives such as dimethylsulfide, dimethyldisulfide, methylmercaptan, or hydrogensulfide. These compounds are found in UHT milks produced in indirect heating plants in concentrations of up to 100 µg/L. The compounds are responsible for the characteristic "cooked" flavor of such milks. In the direct UHT-process, most of the volatile sulfur-derivatives are removed during the application of vacuum in the expansion step.

Formation of Intramolecular Cross-Links Involving Lysine [80, 81]. Phosphoserine residues in casein can undergo heat-induced elimination of the phosphate group in the β-position of the side chain, leaving a highly reactive dehydroalanine residue. The reactive double bond forms a cross-link with a proximate lysine ϵ-amino group. The corresponding lysine derivative, lysinoalanine, is the chemical trace of this reaction after total acid hydrolysis of the (cross-linked) proteins. The resulting lysinoalanine crosslink reduces the proteolytic digestibility of the protein. Significant amounts of lysinoalanine can be found in caseinates, probably as a consequence of temporary exposure of the casein to alkaline pH, during its production.

Lysine ϵ-amino groups can also undergo condensation with asparagine and glutamine residues to form isopeptide bonds with simultaneous release of ammonia from the amide group of asparagine or glutamine. This reaction is particularly favored by heating of milk proteins in the dry state or during the drying process in hot air.

Denaturation of Whey Proteins [12, 13, 83]. Heat treatment of milk above 65 °C causes the denaturation of whey proteins. Heat sensitivity of the major whey proteins decreases in the following order:

immunoglobulins > serum albumin > β-lactoglobulins > α-lactalbumin

Milk pasteurization leads to significant denaturation of immunoglobulin and serum albumin, while the effect on β-lactoglobulin and α-lactalbumin is negligibly small. As shown in Table 11, the content in undenatured β-lactoglobulin in pasteurized milks is ca. 3000 mg/L, or close to the initial content of the raw milk. In UHT milks, 60 – 90 % of the total β-lactoglobulin is denatured, while in retorted milk denaturation of all whey proteins is complete. Heat denaturation of β-lactoglobulin in whey leads to oligomerization and polymerization of the protein, denaturation in milk leads to complexation between β-lactoglobulin and casein micelles. In this complex, intermolecular disulfide bonds link denatured β-lactoglobulin to κ-casein of the micelle. Complex formation between the serum proteins and the casein micelle is pH dependent and reaches a maximum at pH 6.6 – 6.7. If the pH of the milk is raised prior to heat treatment, a major part of the κ-casein dissociates from the micelle and reacts with β-lactoglobulin in the serum phase. Such a reac-

tion reduces the heat stability of the milk, as a κ-casein depleted micelle is more sensitive to aggregation induced by heat treatment in presence of calcium ions.

Modification of Lactose. At temperatures >90 °C (e. g., during UHT or retort sterilization) lactose is epimerized) to lactulose (4-*O*-β-D-galactopyranosyl-D-fructose; → Lactose and Derivatives, Section 2.1), which is entirely absent in unheated milk. The measured content of lactulose represents a chemical indicator for the heat history of processed milk. Lactulose itself is not entirely stable but is converted, under the influence of heat, to galactose and formic acid.

The lactulose content of a sterilized milk allows to make an easy distinction between UHT sterilized and retorted milks, as well as between high-pasteurized and UHT milks (Table 11).

A lactulose concentration of 1 g/L milk corresponds to the isomerization of ca. 2 % of the total milk lactose. Lactulose can undergo Maillard reaction with lysine ϵ-amino groups; however, the reactivity of lactulose is lower than that of lactose.

Modification of Milk Fat [73]. Milk fat is relatively stable towards heating. There are no major chemical changes known to result from standard dairy heat processing of milk. On the other hand, some effects of heat treatment on the fat globules and their membrane are known. Heat coagulation of the "agglutinins" (fat globule aggregating immunoglobulins) interferes with cluster formation and decreases the velocity of cream separation. As a result of heat treatment, some of the membrane phospholipids may be transferred to the soluble phase of milk. Direct UHT heating of whole milk has a homogenizing effect, as the strong turbulence during steam injection followed by an exposition to cavitation forces during the expansion step, causes disruption of fat globules.

Changes in Mineral Equilibrium [73]. Milk is supersaturated in calcium and phosphate by virtue of the ability of the casein micelle to keep micelle-linked calcium phosphate in a colloidal state. In the milk serum calcium is mainly chelated by citrate ions, and, to a lesser extent, by phosphate ions.

When milk is heated, the pH is lowered due to lactose degradation and the formation of organic acids, such as formic acid. Tricalcium phosphate is formed and some of it may be precipitated from the milk. Calcium phosphate deposits on heat exchangers and in evaporators (fouling) are frequently occurring in dairy plants and are formed during the processing of milk as well as of whey. The deposits usually are not purely mineral but also contain significant amounts of protein. This reaction is responsible for the formation of calcium phosphate deposits during storage of UHT milks.

7.4. Homogenization [4, 12, 13, 85, 86]

Raw milk forms, upon standing, a cream layer within less than an hour. The speed by which the individual fat globules rise to the surface increases with their size and further depends on the density difference between the milk fat (0.93 g/mL) and the aqueous phase of the milk (1.034 g/mL), as well as on the viscosity of the milk itself. In quantitative terms, the creaming velocity v (cm/s), follows Stokes law:

$$v = [d^2(\varrho_d - \varrho_c)g]/18\eta$$

where ρ_d is the density of the dispersed phase (milk fat), ρ_c the density of the skim milk (continuous phase); η the dynamic viscosity of the milk and g the gravitational acceleration (9.81 m/s^2). As the diameter of the fat globules enter the equation in the second power, a reduction in fat globule size has a large effect on creaming velocity. The fat globule size in raw milk varies from about 1 to about 10 µm and application of Stokes law to such diameters leads to creaming times of several hours. Reason for the more rapid creaming of raw milk is the clustering of fat globules (see Section 3.1.2). To achieve sufficient creaming stability for pasteurized milks with a relatively short shelf life, reduction of fat globule size to a mean diameter of 1 – 2 µm is sufficient, while the long shelf life UHT milks require a much greater reduction in fat globule size (0.7 µm or less).

Another effect of homogenization is the large increase in exposed fat area, which greatly favors the action of lipases. For this reason, it is indispensable to first pasteurize the milk (in order to inactivate the lipase), prior to homogenization. The shear and cavitation forces leading to the

disruption of the milk fat globules also disrupt the native MFGM. The released membrane material will adsorb to newly exposed fat surface. However, the increase in uncovered fat surface is so large that the material derived from the MFGM is insufficient to cover it. Protein present in the continuous phase of the milk will adsorb to the newly exposed interface. This rapid adsorption of proteins from the continuous phase of the milk prevents a coalescence of the smaller fat globules after passage through the homogenizer's valve. In the homogenized milk, the fat globules are coated with a secondary membrane with a different protein composition than the original MFGM. This has practical importance in recombined milks in the production of which butterfat or vegetable fat (filled milks) is being homogenized with skim milk solids.

The relationship between the homogenization pressure and the fat globule size for fat contents of up to about 12 % is the following:

$$\log d_{\mathrm{v/s}} = \mathrm{const} - 0.6 \log P$$

$d_{\mathrm{v/s}}$ being the volume/surface related diameter and P the homogenization pressure. In the homogenization of milk, an increase of the homogenization temperature above 50 °C has little effect on homogenization efficiency, while at higher fat contents such as in creams, homogenization temperatures $\geq$ 65 °C lead to a better result.

Standard dairy homogenizers (Fig. 4) are operated at pressures of 5 – 30 MPa. Usually homogenization is carried out in two stages, a first stage at 15 – 20 MPa, followed by a second stage operated at lower pressure (typically 5 MPa). The principle of the homogenizer valve is shown in Figure 5. The dimension of the slit through which the milk is forced with pressure, is in the range 20 – 300 µm, depending on the type of homogenizer. A product velocity of 50 – 250 m/s is reached within the narrow slit of the homogenizer head, the average residence time in the slit is in the range of a few microseconds. In the aseptic design (see 7.4), the homogenizer's head can be exposed to pressurized steam to guarantee sterility of upstream UHT-heated milk.

Figure 5. Homogenizer head (reproduced from [4] with permission)
a) Outer ring; b) Homogenizer ring; c) Core; d) Gap

In addition to prevent the creaming in milk and dairy products, homogenization has further desirable effects such as:

Figure 4. Milk homogenizer (reproduced from [4] with permission)
a) Crankshaft; b) High-pressure cylinder block; c) Piston rings; d) Pistons; e) Homogenizer head; f) Pressure setting lever; g) High-pressure manometer

- To increase the whiteness of milk and milk products by an increase in light scattering due to a higher number of fat globules;
- To improve the whitening effect of creams in coffee or tea;
- To improve the "mouthfeel" of milk products by increasing their smoothness and to reduce "grittiness" caused by heat-induced formation of aggregates.

Disadvantages are the increased sensitivity to lipolysis and an increased photosensitivity of the milk fat. Homogenization decreases to a certain extent the protein stability of milks, particularly evaporated milks, during heat treatment [87]. This is due to the formation of aggregates of protein-loaded fat globules during the heat treatment.

Homogenization of cream has the desirable effect to increase its viscosity, but the formation of clusters due to "sharing" of fat globule adsorbed protein, reduces the coffee stability of the homogenized cream. This feathering effect can be controlled by a second, aseptic homogenization of the UHT cream at a low pressure.

7.5. Separation Processes

Fractionation of milk components by either membrane- and/or ion exchange processes is used to produce "tailor-made" milk fractions for specific uses, or to replace conventional processes. Membrane technologies (→ Membranes and Membrane Separation Processes, Section 4.1) have a particularly high importance in the modern technology of milk fractionation.

7.5.1. Microfiltration [68]

Among membrane processes, microfiltration bridges between ultrafiltration and traditional dead-end filtration. The particle size range covered by microfiltration goes from about 0.1 µm to ca. 5 µm.

Thus, microfiltration, at its upper range, removes particles like fat globules, bacteria, bacterial spores and other, particulate milk components such as somatic cells or cell fragments. Such membranes produce ultra-clean milks with very low counts of viable germs or spores, with improved taste properties due to a minimum heat treatment, and with an increased shelf life when refrigerated (see Section 7.2).

Microfiltration membranes with lower pore sizes from 0.1 – 0.2 µm split skim milk into a casein-rich retentate and a "native" milk serum, devoid of casein. Casein micelles are sufficiently large to be rejected by the membrane, while the soluble serum proteins pass across it. The micelle fraction produced in this separation process has excellent cheese making properties, while the corresponding permeate fraction is a high quality source of native whey proteins. It can be further fractionated for isolation of specific whey proteins such as purified β-lactoglobulin, α-lactalbumin and others (see Section 9.3.4).

7.5.2. Ultrafiltration [88]

Ultrafiltration (UF) is applied to both skim milk and whey, with the objective to concentrate the respective protein components. Both polymer and mineral membranes are used for this purpose. Pore size of UF membranes are in the 10 – 100 nm range and provide cut-off values for spherical molecules between molecular masses of 10^3 to about 10^6.

Ultrafiltration of milk [89] is mainly applied to concentrate protein (and fat) to a level desirable for further processing into milk products such as fresh cheeses, milk powders, or yogurts. Lactose and soluble minerals and NPN are progressively removed with the permeate during this operation. UF is used to increase the protein content of cheese or yogurt milks for optimum product yield and texture improvement. Protein enrichment is useful to regulate the cheese yield throughout the seasons during which the protein content of the milk varies. In yogurt production, UF is an alternative to the addition of skim milk powders with the purpose to increase the protein and solids content in set style yogurts. As caseins and whey proteins are completely retained by the membrane during UF of milk, the mass ratio casein:whey protein is not being modified.

Ultrafiltration is applied to concentrate cheese milk to a level of solids (35 % or higher) at which curd formation proceeds without separation of serum. In this "pre-cheese process" retentate is directly transformed into a cheese

curd by addition of starter or rennet, or both. This process is advantageous for production of some fresh cheeses, as the draining of the serum can be avoided and the protein recovery is increased. The presence of whey proteins in the curd can however lead to texture defects or flavor problems in ripened cheeses. In a more recent version of the "pre-cheese process", the cheese milk is first heated and the casein coagulated, prior to its concentration on the membrane.

Ultrafiltration of Whey [111]. Since the 1960s UF has been used to recover the whey proteins in an essentially undenatured form from cheese whey or from casein whey (see Section 9.3.5). At a later stage, UF has become applicable to produce total milk protein concentrates (MPCs) from skimmed milk. In both processes, a protein-free permeate is produced which is mainly composed of lactose, minerals, and NPN. Such permeates can be used as a raw material for lactose production or, in most cases, are employed as animal feed.

7.5.3. Nanofiltration and Reverse Osmosis

Both processes use composite type polymer membranes such as composites of polysulfone or polyamide. The pore size of the nanofiltration membranes is in the range of a few nanometers, while reverse osmosis membranes have even lower pore sizes (0.1 – 1 nm).

Nanofiltration (NF) systems are operated at medium pressures in the range of 1 – 5 MPa. The membranes have selective permeability for minerals; i.e., high permeability for monovalent cations and anions and lower permeability for bivalent cations. Lactose is retained to a large extent, if not completely. These properties make NF interesting in pre-concentration of whey to about 20 % total solids. At the same time, a reduction of about 60 % of Na^+, K^+, and 30 % reduction in Ca^{2+} can be achieved. The process is often used to pre-concentrate the whey in a cheese factory to reduce transport volume for further dispatching to more or less distant whey processing plants.

Reverse osmosis (RO) membranes are only permeable to water but not to minerals, thus, RO is a pressure driven concentration process. The applied pressure has to compensate the osmotic pressure of the whey or milk solutes (mainly lactose and minerals) and to reverse the flux of water in the direction of the permeate fraction. Pressures of 5 – 10 MPa are required to achieve this (the osmotic pressure of a 30 % lactose solution is already near 4 MPa). In terms of energy, NF and RO are more economic than evaporation, as far as concentration to a certain level of solids (20 – 30 %) is concerned. In the concentration of whey, pre-concentration by RO is often combined with final concentration to >50 % solids on an evaporator.

7.5.4. Ion Exchange Processes (→ Ion Exchangers)

The application of ion exchangers in the food and dairy industry requires a high chemical stability of the resin, in order to avoid any migration of resin monomers or components into the food product.

Demineralization of Whey. Objective of the process is to reduce the mineral load of whey to the extent required for its use in human foods; incorporation of whey in various food products is, due to its high salt content problematic.

For the use of whey in the production of infant formulas, demineralization is mandatory in order to reach lower mineral levels compatible with an infant formula composition.

Whey demineralization often uses a combination of ion exchange and electrodialysis. The ion exchange process consists of two stages, a first cation exchange step, in which whey cations are exchanged against resin H^+ ions. In the second step the whey anions such as chloride, sulfate and phosphate, are exchanged for resin OH^-. The resin used is typically a sulfonated polystyrene resin:

Cation exchange step:

$$\mathrm{Resin{-}SO_3H{+}KCl} \rightarrow \mathrm{Resin{-}SO_3^-K^+{+}HCl}$$

Anion exchange step:

$$\mathrm{Resin-N(R_2)-OH{+}HCl} \rightarrow \mathrm{Resin{-}N^+(R_2)\,Cl^-{+}H_2O}$$

The demineralization efficiency of this process is high; it has to be accounted for some loss

of NPN and a very minor part of the true protein. Main drawback of the process is the need for large volumes of acids and bases for resin regeneration, connected with a high wastewater load.

Partial Demineralization of Milk. Ion exchange allows to obtain a partial replacement of calcium ions with sodium ions, with a simultaneous reduction of milk acidity. Calcium reduced milk has a higher heat stability. In order to split the calcium phosphate, a weakly acidic ion exchange resin is used which binds Ca^{2+} more strongly than Mg^{2+} or monovalent cations. Ion exchange processes can be applied to remove radioactive Cs or Sr ions in radioactively contaminated milk.

7.5.5. Electrodialysis (→ Membranes and Membrane Separation Processes, Chap. 3; → Membranes and Membrane Separation Processes, Section 3.7)

In electrodialysis (ED), low molecular mass ions migrate in an electrical field, across cationic and anionic membranes, the membranes being arranged in alternating manner in the ED stack, between the cathode and the anode. The membrane compartments are fed with brine and product to be demineralized, respectively, also in alternating manner. In the stack, anion exchange membranes repulse the migrating cations and let pass the anions; inversely, the cationic membranes are permeable for anions while they repulse the cations. The efficiency of demineralization of the feed is proportional to the intensity of the electrical field; the latter depends on a sufficiently high conductivity of the product stream. Main application of ED in the dairy industry is the demineralization of whey.

In order to increase the conductivity, whey is often preconcentrated to about 20 % total solids, prior to its demineralization by ED. The efficiency of demineralization in ED is a function of ion mobility and depends on the charge density of an ion. The efficiency is highest for K^+, Na^+, and Cl^-, while it is less efficient for Ca^{2+} and Mg^{2+} or phosphate ions. The ash content of skim milk (ca. 0.8 %) can be reduced by several passes of ED to less than 0.3 %.

7.6. Cleaning and Disinfection [4, 12 – 14] (→ Cleansing Agents, Chap. 2)

Cleanliness and perfect hygiene are required for consistent production of stable, high-quality products. Therefore, cleaning and disinfection are of fundamental importance for a dairy. After cleaning and disinfection, thorough rinsing with pure water is required to prevent contamination of the products and corrosion during holding.

Cleaning. The cleansing agent should swell proteins, emulsify fats, dissolve mineral residues, and make surfaces wettable for pure washing water without chemically or mechanically attacking them. Cleansing agents used in practice consist of a mixture of chemicals that dissolve proteins and milk stone which consists mainly of calcium phosphate (70 %); surfactants that wet and dissolve dirt particles and emulsify fat; corrosion inhibitors; and softeners that reduce water hardness. Large production plants are subjected to cyclic cleaning without disassembling (CIP = cleaning in place) which lends itself to automation.

Acidic cleansing agents are mainly effective against inorganic residues such as milk stone. Aqueous 0.5 – 5 % solutions of inorganic acids (nitric, phosphoric, and hydrochloric acids) and organic acids (citric, levulinic, gluconic, and tartaric acids) are used.

Alkaline cleansing agents are particularly effective in the swelling, dispersion, and dissolution of proteins; they also have a bactericidal effect. Silicates are added as corrosion inhibitors and polyphosphates function as emulsifiers and counteract water hardness. Alkaline cleansing agents contain sodium hydroxide, sodium carbonate, sodium ortho-, meta-, and polyphosphates, as well as sodium silicates in concentrations of 0.2 – 2 %.

Surface-active cleansing agents (alkyl sulfates, alkyl sulfonates, quaternary ammonium bases) improve permeative and wetting power, increase the dirt-suspending power, emulsify fat, and to some extent disinfect.

Chelating agents (ethylenediaminetetraacetic acid and nitrilotriacetic acid) prevent the precipitation of insoluble calcium and magnesium salts and reduce water hardness.

Table 12. Wastewater load from dairy processing [12]

Parameter	BOD_5, mgO_2/L	COD_5, mgO_2/L	TOC, mgC/L	Total solids
Milk (3.5 % fat)	114	183	70	12.5
Skim milk	90	147	62	9.2
Sweet whey	42	65	27	6.2
Acid whey	35	60	25	5.6
Cream (30 % fat)	400	750	186	38
Typical BOD load, kgO_2/t				
Milk processing (dairy)	0.5 – 3			
Milk drying	0.4 – 1			

Disinfection. Every cleaning procedure must be combined with a disinfection step to destroy all vegetative cells of bacteria, bacilli, yeasts, and molds. The most important disinfecting agents are:

1) Hypochlorite and chloramine: these solutions are strongly germicidal but also corrosive
2) Quaternary ammonium compounds and ampholyte salts
3) Hydrogen peroxide: primarily used for surface sterilization of packaging materials (15 – 30 % solution at temperatures up to 80 °C)
4) Hot water and superheated steam: temperatures of 120 – 130 °C are needed for complete sterilization

7.7. Water Treatment

Water Quality in Dairy Processing Plants. The water used in dairy plants must have drinking water quality; that means it is free of pathogenic bacteria, has < 300 total CFU/mL and no coliform germs in 100 mL.

Local water supply often provides hard water, unsuitable for dairy processing. For many membrane operations such as nanofiltration, ultrafiltration or microfiltration, partially or completely deionized water is being used.

"Milk water" is condensate formed during milk concentration on falling-film evaporators. The condensate from the first or eventually the second effect of evaporators is sufficiently pure, to be fed feed back into the steam generator's water reservoir.

Wastewater [14, 152 – 157]. A milk processing plant produces approximately twice as much wastewater as milk processed in the plant or even three to six times this quantity if the cooling water is also fed into the wastewater. Measures taken in the plant (e.g., the collection of washwater for animal feeding, repeated use of the butter washwater, and utilization of byproducts) can reduce the amount of wastewater by approximately 30 %. The BOD_5 and TOC values of some milk constituents and milk products are given in Table 12.

8. Fluid Milk

Fluid milks include plain milks from raw milk to heat treated consumer milk of different fat contents.

8.1. Consumer's Milk

8.1.1. Legal Classes of Consumer's Milk

The *European regulation* [90] has the following definitions for consumer milks. *Raw milk* is milk which was not been heated above 40 °C. *Whole milk* is milk that has been heat treated (pasteurized or sterilized). It can be adjusted in its fat content: *nonstandardized whole milk* has an unchanged fat content but not less than 3.5 %; *fat-adjusted whole milk* has a modified fat content but not below 3.5 % and the actual content is indicated on the package.

Partially skimmed milk is heated milk with an adjusted fat content which is ≤ 1.8 % and ≥ 1.5 %.

Skimmed milk is heated milk with a fat content of maximum 0.5 %.

In comparison with these European definitions, the minimum fat content of whole milk in the *USA* is 3.25 %; *reduced-fat milks* have fat contents of 2 %, *low-fat milks* of 1 %, while skim milk has ≤ 0.5 % fat and may be called "fat free".

8.1.2. Characterization According to Heat Treatment [91]

Pasteurized milks have received heat treatments sufficient to guarantee the inactivation of pathogenic microorganisms (see Section 7.3.1). Typically milk is continuously heated at 72 °C for 15 – 20 s.

The effect of pasteurization is controlled by the alkaline phosphatase activity test, which must be negative. Pasteurized milk must, on the other hand, give a positive peroxidase test.

The International Dairy Federation (IDF) [92] defined a routine method to determine alkaline phosphatase activity in milks. The colorimetric method can detect a contamination with as little as 0.5 % raw milks. A more sensitive fluorimetric method has been developed which can detect the contamination of pasteurized milk with as little as 0.01 % raw milk [93]. According to EC directive 92/46 [75], pasteurized milks, besides giving a negative phosphatase test do not contain measurable amounts of lactulose. It has also been suggested to use the content in undenatured β-lactoglobulin to fix the upper limit of adequate pasteurization, while the phosphatase test is targeted to define its lower limit. There is not yet agreement between different countries on the exact value for the lower limit. Pasteurized milk contains ca. 3000 mg of undenatured β-lactoglobulin per kilogram, the β-lactoglobulin content in unheated milk varies from 3300 – 3500 mg (Table 11).

UHT milks are sterile milks, which are packaged aseptically into sterilized, hermetically sealed containers. The UHT process is aimed to destroy all microorganisms in the product, which can be stored at room temperature.

The minimum lethal effect on heat resistant spores required is $F_0 = 3$ min. In most UHT processes, this is achieved with heating temperatures of 130 to 150 °C. The lower limit of this range is mainly exploited by indirect heating plants, while the higher end of the range is the area for direct heating by steam injection or infusion processes. The minimum lethal effect is reached at 135 °C in 7 – 8 s holding time, while at 148 °C, 0.4 s would be sufficient. In the practice, the applied heating conditions considerably exceed the minimum requirement of $F_0 = 3$ min; this has the objective to guarantee a sufficient shelf life under nonrefrigerated conditions.

The content in lactulose is the chemical indicator to differentiate between pasteurized and UHT milks. While pasteurized milks must not contain significant amounts of lactulose, directly sterilized UHT milks show lactulose contents of a few hundred milligrams per kilogram. The lactulose content of indirectly processed UHT milks is much higher (usually above 500 mg/kg). UHT heating results in extensive (>90 %) denaturation of the whey proteins; thus the content in undenatured β-lactoglobulin of UHT milks is usually below 100 mg/kg.

Despite the somewhat lower taste profile of UHT milks if compared with pasteurized milk, UHT milks have increased their market share at the costs of pasteurized milk during the last years (convenience driven preference of UHT milk).

In-Bottle Sterilized Milks. In several countries, retort sterilization of consumer's milk is current practice. This is mainly achieved in glass bottles, but alternatively sterilizable polyethylene packages can also be used.

Retorted milks differ from UHT milks by their even higher lactulose content ($\geq$ 1000 mg/kg). The retort process results in a somewhat caramelized taste, due to considerable Maillard reaction (see Section 7.3.2.3).

UHT sterilization may be combined with a poststerilization in the package, in this way the heat load in the final heat treatment can be significantly reduced compared with that of standard retort sterilization.

8.1.3. Modified Consumer's Milks

For the *European Community* EC directive 2597/97 [90] intends that the following modifications of milk composition are authorized for the production of special purpose consumer milks: milk may be enriched in milk protein, in minerals or vitamins; or milk may be reduced in their lactose content by (enzymatic) hydrolysis of the lactose.

The EC member states are, however, free to restrict or forbid such modifications of the milk composition in their proper countries.

In the *USA*, supplementation of consumer milks with vitamin D is optional practice, while

low fat consumer milks or fat free milks must be fortified with vitamin A.

In the last years, *lactose hydrolyzed* consumer milks have reached the market, intended for consumers that are lactose intolerant (see Section 6.2).

Since milk and milk products are being promoted as ideal dietary sources of calcium, dairies in all parts of the world have started to produce and market *calcium enriched* milks (pasteurized, UHT, or powdered) with total calcium contents of 1.8 – 2.0 g/kg, instead of the natural 1.2 – 1.3 g/kg.

8.1.4. Packaging of Fluid Milks and Milk Products [94, 95]

Packaging materials must be waterproof, have low oxygen permeability, provide sufficient light protection and be nonpenetrable by bacteria.

At present, laminated paperboard packages have the largest share among all packages (about 60 % in Western Europe). Plastic bottles, plastic cups, and glass are next important package materials. New trends in packaging of liquid dairy products are driven by cost factors and environmental considerations. Pouches could gain substantial market share for consumer milks due to their cost saving potential. For UHT milks and other shelf stable milk products, plastic based packages are especially suitable as these allow to create specific barrier properties and offer new possibilities for distinctive milk packaging concepts.

The requirement to reduce waste volume encourages the introduction of biodegradable packages, such as recently introduced for yogurts.

8.2. Reconstituted and Recombined Milk

Recombination is the production of consumer milks or milk products from milk powder (whole milk powder or skim milk powder) and a fat source, either anhydrous milk fat or vegetable fat.

If milk nonfat solids are recombined with vegetable fat, this is called *filled milk*.

Recombination has a high economic importance in nondairy countries with no or an insufficient supply in fresh milk (see Chap. 12).

The key raw materials for recombining are, besides whole milk powder, skim milk powder (SMP), and anhydrous milk fat (AMF). In the production of consumer milks by recombination, low heat or medium heat skim milk powders are the preferred raw material to achieve a good milk flavor of the recombined milk, resembling that of pasteurized fresh milk.

Two alternative procedures are used to produce recombined milk:

1) Anhydrous milk fat or butterfat is liquefied and added to an aqueous dispersion of skim milk solids, at about 45 °C. The mixture is homogenized at a temperature of 55 – 65 °C at 25 MPa and then subjected to a pasteurizing or an UHT heat treatment.
2) Anhydrous milk fat or butterfat is dispersed together with part of skim milk solids to give a cream with a fat content of about 30 %. The cream is homogenized at 20 MPa/5 MPa at 55 – 60 °C and then diluted to the desired SNF/fat ratio by mixing it with a skim milk dispersion.

Filled Milks. In order to save costs for expensive (imported) milk fat, and use local fat sources in its place, filled milks are produced and marketed in many nondairy countries. In order to provide cream flavor, buttermilk powder is often added during the recombination process.

Toned Milks. Toned milks are obtained by mixing whole fresh milk of local provenience with skim milk powder, to achieve a defined fat- and protein content in the final mix. An example is the production of mixed milks in India, from skim milk powder added to liquid high-fat buffalo's milk. This allows to obtain a more balanced protein : fat ratio.

9. Milk Products

According to EC directive 1898/87 [96], the designation "milk product" is, in addition to dried or evaporated milks, applicable to caseins, cheeses, cream, butter and buttermilk, butter oil, and anhydrous milk fat. Milk products are also fermented milks such as yogurt, kefir, or kumis.

Figure 6. Multistage falling film evaporator (reproduced with permission of APV Nordic, Anhydro)
a) Calandria; b) Vapor separator; c) High-pressure fan; d) Plate heat exchanger; e) Condenser; f) Preheater

The delimitation between "milk products" and "milk containing other products", resulting from mixtures between milk, whey, and nonmilk food components is set at 30 % nonmilk solids.

9.1. Flavored Milk and Milk Beverages [14, 97]

Fluid milks may be combined with ingredients such as cocoa powder, chocolate, vanilla or fruit extracts and fruit juices. Milk beverages may contain thickeners and gelling agents (gums, carrageenans or chemically modified cellulose), in order to suspend insoluble or marginally soluble ingredients. They often also contain sucrose.

"*Chocolate milks*" are by far the most prominent among this category of products. A typical chocolate milk contains 1 – 3 % of cocoa powder, 3 – 6 % of sucrose and some hydrocolloid type stabilizer.

Cocoa particles will sediment in the milk beverage very rapidly, unless the suspension is stabilized by the addition of a thickening agent. In the case of pasteurized chocolate milks, the thickener is usually starch, gelatin or alginate, while for UHT chocolate milks, stabilization is based on the use of carrageenan (0.2 – 0.3 wt %). Retorted chocolate milks are also produced, in this case the preferred stabilizer is modified cellulose.

Fruit milks are combinations of milk with fruit extracts or fruit aromas. The content of all nonmilk ingredients is regulated by legislation. It must not exceed a certain value, e.g., 30 % according to German legislation.

9.2. Evaporated (Condensed) Milk [4, 98]

Concentration and drying of milk leads to products with a smaller volume and a longer shelf life. In the case of evaporated milks sold in cans or plastic cups, shelf stability is achieved by a sterilization step. In the case of sweetened condensed milk, product stability and shelf life is guaranteed by adding sugar to the extent where a sufficiently low a_w is reached. First attempts to extend the shelf life of milk by removal of water can be traced back to the early nineteenth century.

9.2.1. Technology of Concentration by Evaporation [4, 12 – 14]

Evaporation in the dairy industry is most often used in conjunction with spray drying. The most frequently used evaporator is a *falling film tubular evaporator* consisting of several stages ("ef-

fects"). The vapor consumption needed to evaporate a given volume of water from milk decreases with the number of effects, as the heat of the vapor from one effect can be reused in another effect, after compression of the steam in a thermal or mechanical steam compressor.

The scheme of a multiple-stage falling film evaporator is given in Figure 6. By applying vacuum to the individual effects, the boiling temperature can be kept low: between 70 and 40 °C; the highest temperature prevailing in the first effect. For the production of evaporated milks, the concentration factor is ≥ 2, as the milk is concentrated to $\geq 20\,\%$ solids non fat (evaporated skim milk) and to a minimum of 25 % solids in the case of evaporated whole milk.

9.2.2. Unsweetened Condensed Milk

The production of evaporated milk includes the stages shown in Figure 7.

The quality of the raw milk used for production of evaporated milk is critical, particularly with respect to the heat stability of the protein and the spore content which should be as low as possible.

The adjustment of the fat: SNF ratio involves the addition of cream or skim milk to attain the desired ratio in the final product. By preheating the standardized milk, bacterial growth during subsequent evaporation is reduced, and the required heat stability for later sterilization of the concentrate is achieved by denaturing the serum proteins at the level of the nonconcentrated milk. The optimum preheating conditions depend on milk quality and equipment factors. The milk is concentrated in a falling film evaporator. The concentrate is homogenized at pressures of 12 – 25 MPa, cooled and cold stored. At this point, a sterilization test with variable concentrations of stabilizer salt is carried out to evaluate the heat stability of the concentrate. Depending on the result of the test, an adequate amount of stabilizer salt (Na_2HPO_4 or another phosphate under E-no. 339–341) is added and the concentrate canned and retorted in a rotating autoclave or in a continuous retort. Typical retort conditions are 121 °C/10 min, corresponding to $F_0 \approx 10$ min. Test cans are stored for 2 to 3 weeks at 30 °C, others are incubated at temperatures up to 55 °C, in order to control sterility.

Figure 7. Flow sheet of production of evaporated milk

Evaporated milk is also UHT sterilized and aseptically filled in paperboard packages.

The legal definitions of unsweetened evaporated milks are shown in Table 13. EC and the Codex Alimentarius have harmonized their definitions of four categories of evaporated milks.

9.2.3. Sweetened Condensed Milk

Sweetened condensed milk (SCM) is essentially evaporated milk to which sugar has been added. It can be produced from whole milk, from skimmed, or from recombined milk.

In order to prevent bacterial growth in the product, the sugar concentration must be $\geq 62\,\%$ in the aqueous phase to assure an $a_w \leq 0.85$.

For a full cream product this corresponds to a sugar content of about 45 %, 11 – 12 % lactose derived from the milk concentrate adds to

Table 13. Legal regulations for evaporated milks and sweetened condensed milks

Product designation	EC [99]		Codex Alimentarius [104]		
	Fat content, wt %	Total solids from milk	Fat content, wt %	Total solids from milk	Milk solids non fat
Unsweetened evaporated milks					
Evaporated milk (whole)	min. 7.5	min. 25	min. 7.5	min. 25	
Evaporated skimmed milk	max. 1.0	min. 20	max. 1.0	min. 20	
Evaporated partly skimmed milk	$>1.0 < 7.5$	min. 20	$>1.0 < 7.5$	min. 20	
Evaporated high-fat milk	min. 15	min. 26.5	min. 15	min. 26.5	min. 11.5
Sweetened evaporated milks					
Sweetened condensed (whole) milk	min. 8	min. 28	min. 8	min. 28	
Sweetened condensed skimmed milk	max. 1.0	min. 24	max. 1.0	min. 24	
Sweetened condensed partly skimmed	$>1.0 < 8$	min. 24	$>1.0 < 8$	min. 24	min. 20
Sweetened condensed high-fat milk			min. 16		min. 14

In the Codex Alimentarius a minimum protein content of 34 %/TS is specific for both, unsweetened and sweetened condensed milks; the Codex Alimentarius also regulates eventual protein standardization.

this figure to give a total carbohydrate content of 56 – 57 %. The solids non fat content of a fat-reduced condensed milk has to be correspondingly increased, in order to reach a similarly high osmotic pressure in the aqueous phase as with the whole fat version.

The safe water : sucrose weight ratio is near 0.6 for all variants of SCM. Lower ratios, although being on the safe side, include an increased risk of lactose crystallization during shelf life.

Legal definitions of sweetened condensed milks are also given in Table 13 [104].

The required amount of sugar is added either in dry form to the standardized production milk, or as a concentrated syrup, during evaporation. The concentrate may be homogenized at a low homogenization pressure, if it appears desirable to regulate its viscosity properties. The final concentrate, after cooling, is supersaturated in lactose, at room temperature. Crystallization of lactose in form of large crystals (> about 10 µm), produces a sandy mouthfeel of the product. In order to avoid this, the concentrate is seeded at 25 – 30 °C with finely ground lactose and cooled under stirring to about 15 °C. After about 12 h at this temperature, crystallization of lactose in form of small crystals is usually completed and the product can be filled. Finished SCM has a yellowish color and a mayonnaise-like consistency. If the package is not opened and recontamination occurs, its shelf life is >1 a.

9.3. Dry Milk Products

Dry milk is a storable form of whole milk, skim milk, or milk fractions. From a world production of ca. 470×10^6 t/a of cow's milk (corresponding to 42×10^6 t/a of SNF), some 6×10^6 t of whole and skim milk powders are produced (corresponding to about 14 % of the total milk SNF world production). A major part of this milk powder is exported to nondairy countries and used for the production of milk products by recombination. Another important fraction is consumed as food ingredient by the food industry.

Further dried milk commodities include whey powders, buttermilk powders, and milk proteins.

9.3.1. Drying Processes [4, 12 – 14]

The objective of drying is to produce a shelf stable powder, with a remaining humidity near 3 %. This low water content provides a high chemical and microbiological stability.

The most commonly used processes to dry milk are spray drying (by far the most important one) and, for some special uses, roller drying. Freeze-drying is normally not used in dairy drying operations.

Pretreatment is quite different for roller and for spray drying. The kind of pretreatment also depends on the type of milk powder to be produced, i.e., whole milk powder, skim milk powder, or another milk product. The main

steps of pretreatment are preheating of the fat-standardized production milk and its concentration by evaporation. A third possible step is the homogenization of the liquid concentrate prior to its drying.

Roller Drying. In roller drying of milk, the concentrate is dried by contact with a steam heated metal drum, the temperature of which is 100 – 130 °C. The evaporated water is drawn off through a hood located above the drums (most versions of roller dryers have two drums rotating in opposite sense). Two main versions exist, the *trough-fed dryer*, depicted schematically in Figure 8 and the *spray-fed dryer* in which the milk is sprayed from a nozzle or a set of nozzles onto the drums. Factors influencing the speed of dehydration are the temperature of the roller surface, the thickness of the product film, and the rotation speed of the drums. Drying is usually complete within 2 – 3 s. Dried milk forms a layer on the drum which is continuously scraped off by blades.

Figure 8. Principle of the trough-fed roll dryer (Just-Hatmaker, reproduced from [4] with permission)
a) Roll; b) Knife; c) Hood; d) Milk concentrate inlet; e) Dried milk

Characteristics of roller-dried milk are the high degree of protein denaturation and Maillard reaction taking place during drying. In the case of whole milk, roller drying also leads to a high proportion of free fat, due to damaging of the FGM. A high content in free fat (≥ 80 % of the total fat) is a desired property for milk powders used in milk chocolate manufacture. Although spray processes leading to high free fat contents have been recently developed, roller drying remains the most used drying procedure for chocolate powders.

Spray drying of milk or milk derivatives involves the following stages:

- Preconcentrated milk (45 – 55 % total solids) is pumped on the dryer and dispersed through a nozzle into a jet of fine droplets (atomization);
- The droplet spray is mixed with a hot air stream which leads to immediate evaporation of the droplets;
- The powder particles are separated from the air stream and recovered at the bottom of the dryer while the humid air is moved out of the drying chamber.
- In a two- or multistage dryer, the primary powder is conducted to an afterdryer in which final drying and eventually an agglomeration of powder particles is achieved on a vibrating fluidized bed.

Drying requires more energy than evaporation. In a multistage dryer, about 1.8 kg of vapor are needed to remove 1 kg of water from concentrate. Due to the less favorable energy balance of the drying process, concentration by evaporation is pushed as high as possible (actual limits for evaporation of whole milk powder are near 55 % solids, for skim milk powder near 50 % solids). Figure 9 shows the scheme of an industrial spray dryer with its main compartments.

A high-pressure pump transports the concentrate (ca. 50 % TS) on top of the drying chamber and forces it through the atomizer nozzle. Different types of nozzles exist: stationary ones and rotating disks or wheels. The hot air also enters the tower on the top. The atomization pressure determines the size of the droplets in the spray. High atomization pressures (>20 MPa) lead to smaller droplets which evaporate more easily but lead also to more powder fines (dust-like particles) which are not recovered in the powder but blown out with the outlet air.

Figure 9. Spray dying tower for milk powder production (reproduced with permission of APV Nordic, Anhydro)
a) Drying chamber; b) Air inlet; c) Concentrate feed and central atomizing nozzle; d) Integrated fluidized bed; air broom for agglomeration; e) Cyclones; f) fluidized-bed afterdryer; g) Sifter (powder outlet)

Lower atomization pressures such as 5 – 15 MPa create larger droplets in the spray and reduce the drying efficiency but impose less shear stress to the concentrate.

The hot air temperature varies between 170 – 250 °C, depending on the type of dryer and the sensitivity of the product to be dried. The outlet air temperature is in most cases 60 – 80 °C. Residual moisture content of the primary powder is governed by the outlet air temperature, which influences also the maximum product temperature, of the powder during its travel through the drying chamber. When the powder arrives on the bottom of the drying chamber, its moisture content is usually between 5 – 7 %. In the APV/Anhydro type of dryer shown in Figure 10 an integrated fluidized bed of particles is formed on the bottom of the chamber on which the powder particles can be agglomerated. The agglomerated (instantized) particles are discharged at the end of the chamber.

Final drying takes place in the afterdryer at an air temperature markedly below that of the main drying chamber (typically 130 – 150 °C). This second stage of drying provides milder conditions for the removal of the remaining more firmly bound water. Here, the powder reaches its final moisture of about 3 %.

Fines removed by the outlet air flow are captured in air-solids separators or cyclones, collected and re-injected into the drying chamber at an appropriate location. In this type of dryer, the fines are moved with an air broom upwards to the wet zone of the drying chamber. By collision with droplets, the dust particles can be condensed with larger powder particles.

Major constructors of industrial dryers are APV/Anhydro AS (Denmark), Niro AS (Denmark) and Laguilharre *SA* (France). The Nestlé "Egron" dryer is operated by the company since the late 1930s in milk powder production plants.

Instantizing designates a drying process leading to "instantly" dispersible powder. Instant solubility is achieved by changing the particle structure (size of the particle, surface, pore structure, and fat binding). Two basic instantizing processes are used: in the *straight-through process* an agglomeration of the powder particles is achieved by collision of droplets and powder particles in different stages of drying. Such collision leads to a sticking together of individual particles to form agglomerates.

Thus, agglomeration is done in the drying chamber of the tower by means of controlled humidity and the collision of thermoplastic particles of different moisture content, followed by afterdrying.

In the *rewet process* powder agglomeration is done by rewetting powder particles with a water spray or with steam and agglomerate the wetted particles on a fluidized bed in an afterdryer (Fig. 10). Thus in the rewet process, agglomeration takes place outside the drying tower, in the afterdryer.

Lecithination improves the wettability of fat-rich powders such as whole milk powders or high fat powders in water. In lecithination a solution of lecithin in butterfat is sprayed against the spray of concentrate in the drying chamber. This leads to formation of a fine surface layer of lecithin on the particle surface and promotes rapid wetting of the powder particles in water.

EU-directive 76/118 [100] allows the use of lecithin (E 322) as a processing aid for milk powder production. The use of lecithin, limited by Good Manufacturing Practice (GMP) is also regulated by the Codex Alimentarius.

Characteristics of Milk Powder [101]. The *maximum moisture content* of milk powders is subject of regulation and a major quality criterion (see Section 9.3.2). Whole milk powder

Table 14. ADMI Specifications for quality of milk powders [106]

	Whole milk powder		Skim milk powder	
Parameter/grade	Standard	Extra	Standard	Extra
Maximum moisture content, %	4	4	5	4
Maximum milkfat content, %			1.5	1.25
Minimum milkfat content, %	26	26		
Maximum titrable acidity, %	0.17	0.15		0.15
Maximum total viable plate count, CFU/g	100000	50000	100000	50000
Scorched particles (disk) *	B (15 mg)	C (22.5 mg)	B	B or better
Maximum insolubility index, mL	1	0.5		1.25

* B, C are different levels (amounts) of scorched particles collecting on the filter disk, compared to an ADMI standard. The values in parenthesis indicate the corresponding mass of retained particles.

freshly filled after drying has usually $< 3.0\,\%$ of moisture. This low moisture content leads to a_w values < 0.2 and provides optimal stability under appropriate storage conditions.

The *bulk density* of the powder is an important property in economic terms. Increase in the powder density gives a more favorable weight:volume ratio and thus reduces packaging costs. Typical densities for whole milk powders range between 0.4 – 0.5 kg/L. Powder density is related to the amount of air included in the particles, but also to powder particle size. For whole milk powders, *particle sizes* vary from < 100 – 500 µm in diameter.

Powder *wettability* is a function of the particle volume and its size. Agglomerated powders have improved capillarity, thus better wetting properties. Wettability is defined as the time in seconds necessary for a given amount of powder to pass an unstirred surface of water [102]. The *dispersibility* of the powder is its ability to disperse into individual particles without leaving any lumps. Agglomeration and protein denaturation strongly influence dispersibility. *Solubility* of the powder describes as to what extent the powder dissolves well in water and forms a stable dispersion with a minimum of sediment [103].

For whole cream or high-fat milk powders, the *free fat content* is another important quality parameter. Free fat is defined as the amount of fat extractable from the powder by a nonpolar solvent such as hexane or carbon tetrachloride. The extractable fat fraction depends on factors such as fat globule coating in the liquid concentrate, fat globule membrane rupture during atomization, migration of free fat in the powder particles during final drying, and on the porosity of the powder particles. When good reconstitution properties are required (see page 38), the free fat content should be as low as possible.

9.3.2. Whole and Skim Milk Powders

The legal definitions of whole and skimmed milk powders according to Codex Alimentarius are documented in the Codex STAN A-5 of 1971.

In addition the American Dry Milk Institute has established quality standards (ADMI quality

Figure 10. Fluidized bed for instantizing milk powder (reproduced from [4] with permission)

standards) for both whole and skim milk powders (Table 14).

Whole milk powder has a minimum milk fat content of 260 g/kg. It is mainly consumed after its reconstitution in water, like fresh milk. Its good reconstitution properties and pleasant milky taste are therefore the most important quality factors. Whole milk powders, unlike skim milk powders, are not otherwise categorized for trade.

Cream powders have a minimum fat content of 420 g/kg and there main use is in confectionery coatings and fillings, but also in the manufacture of dehydrated soups and sauces, in which the use of powdered cream can be advantageous.

Skim milk powder has a maximum fat content of 15 g/kg and is the key raw material for producing milk products by recombination (see Section 8.2). In addition to this, the food industry, particularly ice cream and chocolate manufacturers are major consumers of skim milk powders. The intensity of heat treatment during processing and the corresponding degree of whey protein denaturation, significantly influence the performance of skim milk powders in an industrial application. A classification of these powders according to the extent of whey protein denaturation has been established by the ADMI in 1971. This classification distinguishes three categories of skimmed milk powders: low heat, medium heat, and high heat powders.

The IDF has established a more refined classification with four instead of three heat classes: low heat, medium heat, medium to high heat, and high heat powders. In either classification, the amount of undenatured whey protein nitrogen (UDWPN) expressed in milligrams per gram of powder determines the heat class. On an average, 1 g skim milk powder has 56 mg of total nitrogen, of which ca. 9 mg is from whey protein. While a value of 9 mg/g of UDWPN is normally not found in industrial milk powders (minimum pasteurization requirements required for evaporation already reduce it), powders with 7 – 8 mg UDWPN/g can be produced and are suitable for cheese manufacturing. The largest number of applications will be best covered by medium heat powders; such as the production of consumer milks, yogurt production, ice cream manufacture, and others. For producing evaporated milks or sweetened condensed milks, for use in bakery products or in meat products, high heat powder may be the better choice [107].

9.3.3. Butter and Buttermilk Powders

Butter powders are a powdered form of butter, used mainly as an industrial food ingredient. Butter powder contains $\geq$ 82 % milk fat, some 5 – 7 % of SNF and caseinate which has been used to form an emulsion of sufficient stability to enable its further processing to powder. Processing aids used in the production of butter powders are small amounts of lecithin and citrate.

A functional advantage in industrial use of powdered butter are the good blending properties with flour which facilitate its incorporation in dough.

Butter production from butter powder by recombination, requires the addition of about 15 % water.

Buttermilk powder (BMP) is produced by spray-drying of buttermilk (see Section 9.6) and finds applications in the bakery, confectionery,

Table 15. Composition of dried milk, buttermilk and whey powders [11]

Constituent	Skim milk	Whole milk	Buttermilk	Rennet whey
Protein (N × 6.38), g/100 g powder	36.0	26.0	34.0	12.0
Fat, g/100 g powder	0.7	26.8	5.0	1.2
Carbohydrates, g/100 g powder	51.0	38.0	48.0	72.3
Minerals (ash), g/100 g powder	8.2	6.0	7.9	8.2
Humidity, g/100 g powder	3.0	2.3	3.0	7.1

Phosphorus, g/100 g powder	1.0	0.8	0.9	0.6

* Energy content 17 kJ/g for protein and for carbohydrate; 38 kJ/g for fat.

and ice cream production. BMP represents a dairy source of phospholipids acting as emulsifiers. Thus BMP with high phospholipid content can be used as a dairy ingredient to improve fat emulsification. The typical composition of milk, buttermilk, and whey powder is given in Table 15.

9.3.4. Whey Powders and Permeates [108, 109]

Whey powders have been obtained by spray drying whey of different origins (mainly rennet whey, lactic whey, casein whey). According to its origin, there are compositional differences in whey of different type (→ Cheese, Processed Cheese, and Whey, Chap. 7).

For a typical composition of rennet whey powder see Table 15. A key problem in spray drying of whey is the stickiness of the powder resulting from the strong hygroscopic properties of amorphous lactose and the lactic acid. Whey (total solids content ca. 6 %) is pre-concentrated by evaporation to ca. 60 % solids. At a certain level of concentration, lactose crystallization is induced and α-lactose allowed to crystallize (see → Cheese, Processed Cheese, and Whey, Chap. 7; → Lactose and Derivatives). Whey demineralization is another important processing route (see Section 7.5.4) leading to a key raw material in the manufacturing of infant formulas (see Section 9.3.6).

9.3.5. Milk Protein Powders [110, 111, 116]

Although a widely accepted legal definition of "milk proteins" does not exist at present, a tentative definition has been given by the International Dairy Federation (1988), in which the distinction is made between "milk proteins" and "milk protein products". The former have $\geq$ 85 % protein on dry matter, the latter $\geq$ 50 %. The proximate and mineral compositions of important commercial milk protein powders are given in Table 16.

Milk protein concentrate (MPC) [111] is produced by UF of skim milk and is a concentrate of the total true milk protein; thus the ratio of caseins to whey proteins remains essentially unchanged. During concentration of milk by UF caseins maintain their native, micellar structure, therefore micelle associated calcium and phosphate ions are retained to a large extent together with the protein. Protein contents of commercial MPC's are typically 65 – 85 % based on dry matter (Table 16).

Main end use of MPC is in the protein standardization of cheese milks; protein fortification with MPC leads to more regular curd formation and improved cheese yield throughout the milking season. Other applications are in protein fortification of yogurt milks with the objective to increase the gel strength and texture, and improve water retention properties. Milk protein concentrates are a valuable protein and calcium source for low lactose dietetic food formulations.

Caseins, Caseinates and Coprecipitates [35, 115].

Acid casein is produced through pH adjustment of skim milk to pH 4.6 with mineral acid (HCl or H_2SO_4) or lactic acid. Acidification and curd formation is also achieved by fermentation with starter culture producing lactic acid. The precipitated caseins are separated from the acid whey by a centrifuge process and the curd is washed free of lactose and other non-protein solutes. The washed curd (moisture content is ca 50 %) is then dried. Powdered acid casein has a protein content (N $\times$ 6.38) of $\geq$ 90 % based on dry matter and a rather low mineral content (Table 16). It is entirely insoluble in water, but dissolves if its aqueous dispersion is neutralized with a base. Quality criteria for edible caseins are laid down in Codex Alimentarius STAN A-18 of 1995 (Table 17).

Sodium, Potassium, and Calcium Caseinates [115]. Caseinates are produced by addition of base to acid casein curd up to a pH of about 6.8. Sodium and potassium caseinates are truly soluble proteins the solutions of which have considerable viscosity. In contrast to theses two, calcium caseinate forms a colloidal dispersion in which casein monomers are associated in micelle-like particles; calcium caseinate dispersions have relatively low viscosity.

Caseinates have wide application as protein ingredient in dairy and nondairy food formulations.

Sodium and potassium caseinates are key ingredients in emulsified food systems such as

Table 16. Composition of commercial milk proteins [110]

Milk protein fraction	Process involved	Proximate and mineral composition, g/100 g powder								
		Protein	Lipids	Lactose	Ash	Humidity	Calcium	Potassium	Sodium	Phosphorus
Acid casein	mineral acid precipitation of casein from skim milk	86.8	1.5	0.8	1.2	8.2	0.05	0.09	0.06	0.74

soups, dresses, sauces, or comminuted meat products. They find use in coffee creamers and coffee whiteners.

Calcium caseinate is applied as a nutritional protein and calcium base in dietetic formulations, performance nutrition and clinical nutrition products.

Coprecipitates [115] are produced by calcium addition and pH lowering of preheated skim milk, in a similar fashion as acid casein. In contrast to the former, milk is preheated at 90 – 95 °C for several minutes, in order to denature the serum proteins and by this, achieve their coprecipitation with the casein. Depending on the amount of $CaCl_2$ added to the milk and the pH of precipitation, coprecipitates with variable calcium content are obtained. The pH of precipitation for high calcium products is 5.8 – 5.5, for low calcium products the pH for precipitation is 4.6.

Such a process makes it possible to recover a major proportion of the whey proteins, together with the casein, in form of a protein concentrate. Coprecipitates are sparingly soluble in water and give colloid-disperse systems. Their application is restricted to food systems where good solubility of the protein is less important, such as in dough, bakery, and confectionery products and, to some extent also in meat products.

Rennet casein is produced by curd formation with calf rennet or a microbial rennet, followed by cutting and dispersing of the curd, washing the water insoluble casein, dewatering the dispersion and drying. Rennet casein remains insoluble in water unless the pH is raised above 9.0, and/or chelating agents are added. The major food uses of rennet casein do not required its solubilization but are more based on its heat-induced melting properties. Rennet casein is a raw material for producing imitation cheeses,

pizzas, and other fast food products. Rennet casein and coprecipitates are also processed to textured snack type foods by extrusion cooking in presence of alkali or alkaline earth metals.

Rennet casein has also nonfood industrial uses such as in paper coating.

Whey Protein Concentrates (WPCs) [110, 116, 117]. Ultrafiltration of sweet or acid whey leads to protein concentrates with, depending on the concentration factor and eventual diafiltration conditions used, protein contents ranging from >30 – 85 % on dry solids. Depending on whether the whey was delipidated or not prior to ultrafiltration, the fat content of the concentrates varies from < 1 % to 7 % on dry solids (see Table 16). Ultrafiltration of rennet whey is usually performed at milk pH or at a slightly lowered pH to improve the solubility of calcium phosphates. The concentrates obtained in this way have relatively high calcium and phosphate contents. Ultrafiltration at low pH (pH 3 – 3.5, acid whey) leads to retentates with low mineral content (Table 16). An important difference in protein composition of retentates from rennet whey and those from acid whey is the presence of the glyco-macropeptide fraction in the former. This fraction can amount to 15 – 20 % of the total protein in WPCs produced from rennet whey.

The food uses of WPCs depend mainly on their protein content. Low protein concentrates (30 – 40 % protein/TS) are mainly used as "skim milk replacers" in human nutrition, but also in calf feeding. A typical use of WPC is as a partial substitute of skim milk powder in ice cream production. High protein WPCs (>70 % protein/TS) find major application in dietetic food: infant formulas, clinical nutrition, sports nutrition, etc. It is also exploited for its functional performance (gelling, water binding, foaming) in culinary food as a substitute of egg white.

Whey Protein Isolates (WPIs) [117 – 119] have protein contents of up to 90 % based on dry solids, paired with low fat and moderately low mineral contents (Table 16). Isolates are produced by adsorption of whey proteins to ion exchange resins [118]. In the *Palmer process*, also called *Vistec process* (from Viscose Group, UK), whey at pH $\approx$ 3.5 is contacted with a modified cellulose based cation-exchanger. Following adsorption of the protein, the resin is washed free of lactose, fat and other nonprotein solutes. The protein is then desorbed from the resin by addition of alkali to the mobile phase, which causes the proteins to elute in an anionic form. This isolate is produced commercially in the United Kingdom (Bio Isolates) and in the United States (Davisco, at Le Sueur).

An alternative process, the *Spherosil process*, uses a silica bead substituted with quaternary ammonium groups [119]. Whey proteins are bound to the beads in anionic form. The Spherosil QMA resin was developed by Rhône-Poulenc (France) and is used for commercial production of WPI by Armor Proteins (France). Isolates usually have a bland taste and display high functionality in gelling, foaming, and water binding. Their end uses are mainly in dairy and nondairy culinary food in which they improve water retention, texture properties and mouthfeel.

9.3.6. Powdered Infant Formulas [120 – 122]

In production of powdered substitutes of mother's milk, the key raw materials are solids non fat from bovine milk or whey, together with vegetable fat. The task consists in creating a nutrient composition which approaches that of human milk (see Tables 1, 2, and 5). This requires an adaptation of milk SNF in several respects: The mineral content and the protein content have to be considerably reduced; the fat and the lactose content of the composition must be increased. The mean energy density of mature human milk is about 320 kJ/100 g with 55 % of the energy derived from fat, 38 % from lactose, and only 7 % from protein. The energy density of cow's milk is 275 kJ/100 g and 20 % of the energy comes from protein (protein density of breast milk: 1.6 g/100 kcal or ca. 1 g/dL; current infant formulas have protein densities $\geq$ 2 g/100 kcal ($\geq$ 1.3 g/dL).

The adaptation in terms of global composition is achieved by mixing milk SNF with demineralized whey (see Section 6.1) to achieve the desired protein content (12 – 14 % based on dry solids) and increase the lactose content to 54 – 58 % based on dry solids.

Adaptation in terms of protein quality involves a recombination of casein and whey pro-

Table 18. Protein quality in infant formulas

Protein quality and quantity	Codex [120]	EU [121]	USA	
			Old [122]	New [159]
Protein quality:				
Method of assessment	PER *	EAA ** pattern	PER *	EAA ** pattern
Value	min. 85 % of casein	min. 80 % of BM	min. 70 % of casein	reference pattern
Protein quantity:				
Minimum protein density formula	1.8 g/100 kcal	1.8 g/100 kcal	1.8 g/100 kcal	1.7 g true protein/100 kcal
Maximum protein density	4.0 g/100 kcal	3.0 g/100 kcal	4.5 g/100 kcal	3.4 g/100 kcal

* PER = Protein efficiency ratio (as determined in growing rats).
** EAA = Essential amino acids.

teins leading to a balance of the two categories of protein closer to the one prevailing in human milk. In the latter, noncasein proteins predominate over casein. By mixing adequate proportions of milk SNF and demineralized whey, casein : whey protein mass ratios of 40 : 60 – 50 : 50 can be established. This adaptation is beneficial with respect to the amino acid profile of the protein, coming closer to the one of mother's milk than an 80 : 20 ratio. The reduction of the casein proportion in the formula also leads to formation of weaker curds in the infant's stomach.

The appropriate fatty acid composition of an infant formula can be achieved by mixing vegetable fat such as corn or soybean oil with milk fat. The use of milk fat is not mandatory. The mix must have a linoleic acid content not lower than 0.3 g/100 kcal (418 kJ), or ca. 3.0 g linoleate/100 g total solids (total fat content 26 – 28 %).

The nutrient composition of an infant formula is subject of regulation by Codex Alimentarius, and by specific regulations valid within the EC, and the United States (Infant Formula Act of 1985). The Infant Formula Act regulates minimum and, in some cases, maximum contents of individual nutrients, protein quality, and protein density (see Table 18). While powdered infant formulas are the usual form of this product in most parts of the world, liquid in-can sterilized or aseptically filled, ready-to-feed products and liquid concentrates dominate the market in the United States.

In addition to standard infant formulas a number of *special formulas* have been developed as a response to specific needs in infant feeding, including:

1) Premature or low-birth weight formulas, covering particular nutritional needs of a growing number of premature born infants (higher needs for protein, calcium and polyunsaturated fatty acids).
2) Hypoallergenic infant formulas, recommended for infants with an acquired intolerance to cow's milk proteins, or with a genetic predisposition for allergy. In these formulas, the protein component has been subjected to enzymatic hydrolysis in order to attenuate the allergenic potential of bovine milk proteins [123].
3) Acidified infant formulas, with or without living lactic bacteria. Such formulas are particularly useful in countries where hygienic problems in bottle feeding (insufficient water quality and others) are frequent, because lactic acid efficiently lowers the growth rate of bacterial contaminants.
4) Semi-elemental diets, designed for infants with acute feeding problems of different origin. In such formulas the protein is usually provided in form of an oligopeptide fraction and lactose replaced by maltodextrins. To provide an easily absorbable form of fat, medium chain triglycerides are incorporated in combination with milk or vegetable fat.

9.4. Fermented Milk Products [97, 124, 125]

Fermented (cultured) milk products are among the oldest milk products, resulting in early periods from natural contamination of milk with lactic acid bacteria and yeast. Lactic acid fermentation leads to the development of texture, pleasant taste, and improved storage quality of milk.

Table 19. Properties of yogurt cultures [124]

Starter culture	Temperature optimum for growth, °C	Acidity, % lactate	Lactate isomer formed	Proteolysis	Other characteristics
Streptococcus					
S. cremoris	30	0.5 – 0.7	L(+)	low	creaminess by formation of slime
S. lactis	30	0.5 – 0.7	L(+)	high	
S. thermophilus	>40	0.6 – 0.8	L(+)	weak	diacetyl formation
Lactobacillus					
L. acidophilus	35 – 38	up to 1.9	L/D		
L. bulgaricus	>40	up to 1.8	D(−)	high	acetaldehyde formation
L. brevis	30	up to 1.5	L/D		
L. casei	30	up to 1.5	L(+)	high	
L. helveticus	>40		L/D		acetic acid taste
Bifidobacterium					
B. bifidum			L(+)	low	

Traditional and industrial production of fermented dairy products uses specific bacterial cultures, known as *starters*. Characteristic biochemical properties of the most important lactic acid bacteria used in starter cultures are shown in Table 19.

The health benefits of fermented milk products are long known. More recently, some of the beneficial properties of yogurt and other fermented dairy products have been attributed to the presence of living lactic bacteria, which are believed to act favorably on the intestinal microbial flora of the consumer. The term *probiotic* designates "live feed supplements which beneficially affect the hosts by improving their intestinal microbial balances" [126]. Fermented dairy products produced with probiotic cultures have been put on the market in recent years by: Danone (Actimel), MD Foods (Gaio yogurt), Nestlé (LC1 yogurt), Bauer (LA 7 yogurt), and others. Yakult, the Japanese fermented milk based beverage is being increasingly promoted in Western Europe as a "probiotic food". Anticipated and established benefits of fermented dairy products are reviewed in [127].

9.4.1. Legal Definitions

For yogurt, sour milks, and related fermented milk products, most countries regulate the minimum content in milk SNF and the maximum content of non-milk constituents such as sucrose, or fruit preparations. Thus, the maximum content of nondairy constituents in a fruit yogurt is limited to 30 wt % in the EC. The presence of a minimum viable count of lactic bacteria (*Lactobacillus bulgaricus* and *Streptococcus thermophilus*) in yogurt, is a likewise legal requirement. Milks that have been acidified chemically (by addition of lactic or citric acid) are not classified as fermented milk products. The addition of hydrocolloids such as pectins, carrageenans, and other gums, or gelatin, is furthermore subject of regulation on European [128] or on national level.

9.4.2. Specific Fermented Products

Sour milk is usually made from pasteurized milk by fermentation with mesophilic cultures of *Lactobacillus acidophilus* and other starters with moderate acid forming activity, such as *Streptococcus cremoris, S. lactis*, or *S. thermophilus*. The pH of the fermented, cooled product is 4.6 or lower, the consistency viscous. Sour milks are commercialized with different fat contents.

Yogurt, by definition in the Codex Alimentarius (FAO/WHO 1977), is milk fermented with *L. bulgaricus* and *S. thermophilus* and the microorganisms in the final product must be "viable and abundant". Addition of evaporated milk or milk powder into yogurt milk is current practice.

The characteristic flavor of yogurt is largely due to carbonyl compounds, particularly acetaldehyde (25 – 50 mg/kg), volatile fatty acids, and to some extent, due to acetone (ca. 1 mg/kg) and acetoin. Free amino acids resulting from casein proteolysis by proteases from the starter, amount to 0.3 – 0.5 g/kg and have some contribution to the flavor profile. The lactic acid content of yogurt varies in the range 0.8 – 1.2 %

(36 – 54 °SH), corresponding to the fermentation of about 20 – 30 % of the total lactose in milk. According to the fermentative properties of the starter cultures (Table 19), fresh yogurt contains $\geq$ 50 % of L(+) lactate based on total lactic acid. With increasing age, the proportion shifts in favor of the D(−) isomer due to the higher fermentative activity of *L. bulgaricus* at an elevated acidity. The typical pH of "ripened" yogurt varies from 4.0 – 5.0, according to type of yogurt, fat content, and specific starter cultures used. Low-acidity yogurts have a pH above 4.6, while normal acidity yogurt has a pH $< 4.6 \geq$ 4.0.

The two main types of yogurt are the *set-style yogurt* with a firm gelled texture, and the *stirred-style yogurt*, with a fluid texture of higher or lower viscosity. Fruit yogurts are always of the stirred type. While fermentation for the set-style yogurt must take place in the package (formation of the yogurt gel starts already at pH < 5.5); the stirred-type yogurt is fermented in fermentation tanks. After fermentation at 40 – 42 °C for 3 – 5 h (temperature and duration depend on the cultures used), the product is stirred at a low speed prior to its transport by pumping and filling. A moderate to low shear rate is critical to achieve the desired viscous properties of stirred-style yogurt. The process for production of standard stirred-type yogurt is shown in Figure 11.

Stirring of the yogurt milk during fermentation leads to products with low viscosity (*drinking style yogurt*). Yogurt can be frozen like ice cream. *Frozen-type yogurt* is common in the USA. Stirred yogurt can be dehydrated to give *yogurt powder*. Drying conditions have to be adjusted to guarantee the survival of an important fraction of the yogurt bacteria. Yogurt powder is a food ingredient used in bakeries and the confectionery industry, but also in the production of dairy desserts.

Bioghurt is the trade name of yogurt produced by fermentation with a selected population of starter organisms including *S. thermophilus, L. acidophilus and B. bifidum.* A main property of Bioghurt is that lactic acid is predominantly present as the L(+) isomer, the form considered to be the physiologically active form of lactic acid. As a result of a weak post-fermentative acidification during refrigerated storage, the yogurt has a mild taste.

Bifidus yogurt is the name for a mild tasting yogurt produced mainly in Germany, Japan, and the USA by using selected cultures of *B. bifidum*, *B. longum*, *S. thermophilus*, and *L. delbrueckii.*

Kefir. The name is derived from the Caucasian word *kefy,* meaning pleasant taste. Kefir originates from the Northern Caucasus and was originally produced from both cow's and goat's milk by using kefir grains. Kefir is sour and contains low concentrations of ethanol (0.02 – 0.04 %) and CO_2. Kefir grains contain lactic bacteria and yeast cells immobilized in a polysaccharide matrix. The microflora consists of heterofermentative lactic acid streptococci (*S. lactis*, *S. cremoris*), mesophilic lactobacilli such as *L. kefir*, and *Leuconostoc species*, acetic acid bacteria,and yeasts (*Candida kefir, Kluyveromyces marxianus* and others).

To produce kefir, preheated milk is inoculated with kefir grains and allowed to ferment at ambient temperature (20 – 23 °C) for 10 – 20 h; the kefir grain is then filtered off and the beverage cooled and cold stored. The flavor of kefir is very different from that of sour milk or yogurt; mainly due to the presence of yeasts, formation of ethanol, and CO_2. Formation of CO_2 presents an obstacle to the industrial production and distribution of kefir (blowing up of packages, unless glass bottles are used).

The most important industrial kefir production is in Russia. In this production, a kefir culture is used instead of the grain. The ethanol content of industrial kefir is about 0.02 %.

Kumys, also called Kumiss, Koumiss, or Kymys, originates from central Asia, where it was produced from mare's milk. In today's kumys production (mainly in Russia and the Mongolian plains of central Asia), the beverage is produced from pasteurized mare's milk by fermentation with starter culture. The starter consists of *L. delbrueckii* and lactose fermenting yeast (*Sacharomyces lactis*). In Russia, kumys is also produced from cow's milk [129].

Ymer is a Danish cultured milk product produced from cow's milk with an increased total solids content, to achieve a viscous consistency. The normal manufacturing procedure consists in fermenting skimmed milk with cream starter at 20 – 22 °C until a pH of 4.6 is reached. This

Figure 11. Flow sheet of production of stirred-type yogurt

is followed by cutting the resulting curd and whey removal. Following addition of cream and homogenization at low pressure, the product is cooled and packaged. Another process employs UF to concentrate the protein in the production milk about two-fold. The retentate is fat adjusted (typically 35 g milk fat/L), the mix homogenized and pasteurized. The resulting composition is fermented with cream starter for about 20 h; it has a gel-like consistency [130].

Yakult (registered trade name since 1935 in Japan) is a Japanese fermented milk beverage. After addition of glucose and glycine skim milk is heated at 90 – 95 °C for about 30 min. Following its cooling to 45 °C, the heated milk mixture is inoculated with "Shirota culture" (strain of *L. casei*, isolated by M. Shirota in the 1930s from human intestine).

Incubation lasts 6 – 7 d at 37 – 38 °C. Following fermentation, the product is diluted with water and sugar, gums and lactic acid are added prior to packaging in small cups or tins. Yakult enjoys great popularity as probiotic food in Japan, but it is conquering new European and Asian consumers.

Table 20. IDF Survey on cream definition in various countries [71]

Country	Minimum fat content	Other parameters	Classes according to fat content	Minimum fat content of cream class
Australia	350 g/kg	max plate counts and coliforms	rich cream	480 g/kg
		pH limits, limits for acidity	reduced cream	250 g/kg
			light cream	180 g/kg
			extra light cream	120 g/kg
Switzerland	150 g/kg	SNF minimum 85 g/kg	double cream	450 g/kg
			cream/whipping cream	350 g/kg
			half cream/coffee cream	150 g/kg
France	300 g/kg		light cream	$\geq 120 < 300$ g/kg
Germany	100 g/kg	milk solids can be increased	whipping cream	300 g/kg
UK	180 g/kg		clotted cream	550 g/kg
			double cream	480 g/kg
			whipping cream	350 g/kg
			cream (single c.)	180 g/kg
			half cream	120 g/kg
Netherlands	100 g/kg		whipping cream	350 g/kg
			coffee cream	200 g/kg
			half cream	100 g/kg

Filmjölk is a Swedish type of sourmilk produced from fat-standardized milk by fermentation with buttermilk starter (including *S. lactis*, *S. diacetilactis*, and *S. cremoris*). The resulting product resembles to some extent acidified buttermilk, it has smooth texture and a fresh, acid taste.

9.5. Cream [4, 12 – 14, 131, 132]

Cream is the fat-rich part obtained by skimming of whole milk in a separator. The legal definition of cream and cream types varies considerably from country to country. An overview of legal definitions in different countries has been compiled by the IDF (Table 20). Cream is an oil-in-water emulsion, similar to whole milk. In contrast to whole milk, the dispersed fat volume fraction (Φ) is much higher in cream ($0.1 < \Phi < 0.4$ for most creams, ca. 0.04 in whole milk).

9.5.1. Production

The traditional way of obtaining cream is to let the milk stand until spontaneous rising of the fat globules is completed. Industrial production of cream relies on milk skimming in continuously operated disk centrifuges (see Section 7.2). Depending on the type of cream to be produced, the fat content is adjusted by adding skim milk into cream for fat contents below that produced by the separator (normally $>35 < 40$ %). Cream has to be pasteurized. A negative phosphatase test is achieved with cream of ≥ 20 % fat by holding for 15 s at 80 °C. This treatment also ensures sufficient inactivation of the lipoprotein lipase, of which about one fourth of the total activity remained in the cream after skimming. While homogenization may be omitted for pasteurized cream with relatively short, refrigerated shelf life, it is indispensable for UHT creams with extended shelf life.

Homogenization conditions for creams with >20 % fat must be carefully adapted to provide sufficient emulsion stability (avoid cream plugs in the package), without causing unacceptably high viscosity and, in the case of coffee cream, enhanced flocculation tendency in coffee. Due to the unfavorable protein : fat ratio in cream, high homogenization pressure leads to a large increase of fat surface and causes cluster formation via protein sharing between different fat globules. The formation of such clusters leads to a sharp rise in the viscosity of the cream, which can be attenuated by a second stage of homogenization at a lower pressure [132].

During processing of cream, great attention must be paid not to damage MFG membranes by pumping, shearing, and air introduction. Such damage causes the release of free fat; the latter unfavorably affects several properties of cream. Pumping of cream should be done at temperatures >40 °C, at which the milk fat is entirely liquid. The risk of forming free fat by membrane rupture is highest at temperatures of 20 – 30 °C, where part of the fat has crystallized, while another part of it remains liquid and can coalesces after its release from the globule.

During production of *whipping cream*, attention must be given to the transport of the cream, preferably done at 60 – 62 °C using low shear pumps. Following its pasteurization, the cream is cooled in plate heat exchangers to about 8 °C and then transported (by means of special pumps) to the ripening tanks, where the final cooling without agitation takes place. "Ripening" means fat crystallization in a process requiring several hours. The ripened cream can be further transported to the filling machine once crystallization is almost completed.

9.5.2. Types of Cream

According to the desired functionality, different types of creams with different fat contents are produced and marketed.

Whipping Cream [133]. Whipping of cream becomes difficult if the fat content falls below about 30 %. Problems in whipping can also arise due to seasonal variations in the milk fat composition (summer fat has a lower melting range than winter fat). Good whipping properties include a sufficient volume increase ("overrun") and high stability of the froth without development of syneresis. To achieve a good froth, whipping cream should be kept at 6 °C or lower. In the whipped cream, fat globules associated with the air-water interface stabilize the air bubbles. Due to rupture of the membrane in part of the fat globules, crystalline free fat glues

different globules together to form a protective lamella around the air bubble.

Whipping cream quality is estimated by its overrun (which should be 90 – 100 % of the initial volume), the rate of serum separation and the mechanical strength after a defined whipping time in a standardized beater.

Coffee cream [134, 135], depending on the country of commercialization, have fat contents of 12 – 20 %. Coffee cream with 12 – 15 % fat is also called *crème légère* in France.

These creams are homogenized, to increase their viscosity to a desirable level, and to enhance their whitening effect in coffee or tea (stronger light scattering due to higher number of fat globules).

Homogenization has, on the other hand, the undesirable effect to increase the flocculation tendency of the cream in hot coffee (clustered fat globules form macroscopically visible flocs when aggregated by heat and acid). Adequate combination of distinct heat treatment and homogenization steps is able to minimize this problem.

Spray Cream (Aerosol Cream). Cream in containers under gas pressure is a relatively new development. Using a *bag-in-bottle* package permits to produce an UHT version of the aerosol cream. Bag-in-bottle systems are not pressurized and the outer container is often made of semi-rigid plastic. A so-called *bag-in-can* system is used for pasteurized cream. In the latter system, the propellant gas (e.g., N_2O) is injected in the space between the bag and the outer can, pressurizing the cream in the bag. The structure of the foam produced by the action of a propellant is quite different from that of a mechanically whipped cream.

9.6. Butter [4, 12 – 14]

Legal definitions of butter are not yet fully harmonized between different countries, but the term butter is reserved to a spread made from milk fat only; butter must be obtained either directly form milk or from cream. An EC draft regulation issued in 1991 proposes the following definitions of butters, according to their fat content: butter (80 – 82 % fat), three-quarter fat butter (60 – 62 % fat) and half-fat butter (39 – 41 % fat). Products with < 39 % fat are designated as low-fat dairy spreads.

Mixed fat spreads (milk fat with vegetable fat) require, according to Codex Standard A1 for butter, milk fat contents between >15 % and < 80 % of the total fat.

9.6.1. Production

To produce 1 kg of butter, about 24 L of whole milk need to be processed.

Butter is produced from whole milk or cream according to a process involving distinct stages (see Fig. 12):

1) Production of cream of a standardized fat content (usually near 40 %)
2) Cream pasteurization and ripening (including fermentation in case of sour cream butter)
3) Churning, buttermilk separation and kneading of butter corns into butter.

Figure 12. Flow sheet of butter production

9.6.2. Steps in Buttermaking

Cream Ripening. The adjusted fat content of the cream used for buttermaking depends on the type of process used. For traditional buttermaking, the fat content is 25 – 30 %, for continuous, industrial processes it varies from 30 – 50 % and, in the Alfa process (see page 50), a fat content >80 % is required.

The temperature range for pasteurization is 95 – 110 °C; pasteurization is done continuously without an added holding period. Prior to cooling of the cream vacuum flashing removes undesirable volatiles.

If sour cream butter is to be produced, 1 – 6 % of starter culture is added to the cooled cream in the ripening tank. The typical starter culture consists of *S. lactis*, *S. cremoris*, *S. diacetylactis*, and *Betacoccus citrovorus*. During the ripening and fermentation period of 18 – 24 h, lactic acid formation decreases the pH of the cream to 5.0 – 4.6. The pH of unfermented cream after ripening is 6.0 or higher. Fermentation leads to special flavor notes due to formation of diacetyl (2,3-butanedione) and acetoin. The production of diacetyl occurs mainly when the pH has already dropped below 5.2.

Physical ripening of the cream is a key step in butter production and has the objective to influence the hardness and consistency of the butter. Without this thermal process taking place in the ripening tank, no constant butter quality can be produced throughout the seasons. Due to a significantly higher content of saturated fatty acids in the winter milk, the butter obtained from winter milk is harder and less well spreadable while, due to a higher content in unsaturated triglycerides in summer milk, softer butter is obtained during the summer. The temperature program for cream tempering may be based on its iodine number (see Section 3.1.1). Typical winter cream with a low iodine value, requires a program which leads to less solid fat during the churning operation, by crystallizing out a low melting olein phase which will become the continuous oil phase in the churned butter. This can be achieved by minimizing the amount of mixed fat crystals in the "cold-warm-cold" process (rapid cooling to 6 – 8 °C, gentle warming to about 20 °C, cooling to ca. 15 °C).

When the task consists in making soft (iodine values >39) summer fat harder, an inverse sequence of temperature events is chosen.

Churning of the Ripened Cream into Butter. Butter grains are formed when cream is subjected to high mechanical stress, provided that the fat is present in the fat globules both in liquid and crystallized form. Liquid fat will, after rupture of the fat globule membranes, coalesce to form the continuous phase of the nascent butter.

When the cream is strongly agitated at the butter-making temperature (12 – 15 °C for winter cream and 10 – 12 °C for summer cream) a foam of protein stabilized air bubbles is produced, to which the membranes of the fat globules are drawn. As the air bubbles become smaller during agitation, the foam compacts and this presses liquid fat out of the fat globules. It also favors the rupture of the MFGM. The content of individual fat globules then condenses to form butter grains. The latter will steadily grow to reach a size of a few millimeters. At that stage, buttermilk is drained off and the butter grains are further kneaded to remove interstitial water. "Working" of the butter grains at the same time reduces the size of the remaining, interstitial water droplets, the average diameter of which should be < 10 μm, to prevent bacteria from growing in the remaining aqueous environment (residual water content should not exceed 16 %).

Specific Buttermaking Processes.

Batch type buttermaking in traditional wooden churning cylinders equipped with inside beaters and kneading rolls is presently only of historical interest. Today, metal churns of different technical design are operated in most dairies. Typical capacities of such churns are 8000 – 12 000 L of cream. The churns are filled to about half their volume (to allow for overrun) with stirred, temperature-adjusted cream and operated at selected rotating speed (typically 25 – 30 rpm). About 40 – 60 min are required until the butter grains appear. Buttermilk is drained off through a sieve and the butter grains are washed with cold water, in order to remove nonfat solids. More recent versions of such machines permit the reuse of the washing water several times to reduce the wastewater load. If desired, salt can be added to the butter in form

of solid table salt or a concentrated saline solution. Subsequent kneading of the nascent butter is conducted at a markedly lower speed (10 – 20 rpm) and results in compaction of the butter grains and expelling of surplus interstitial water.

Continuous Buttermaking Processes. The most widely spread process used in Western Europe was initiated by Fritz in 1940 and further developed by Eisenreich (1959). Key features of this process are shown in Figure 13. While the original Fritz process was only applicable to sweet cream, the further development by Eisenreich allows the production of butter from sour cream. The process is based on a double cooled churning cylinder fitted with beaters, in which the cream is rapidly churned. The churned cream then passes on to a separator (rotating screw) where buttermilk is drained. The butter phase is moved through a perforated plate in which the grains are further narrowed, water droplet size is reduced, and the water finely dispersed within the butter. The second "working section" consists of compartments, an injection compartment, a vacuum working section, and a final working stage including a moisture control unit. A nozzle located at the outlet of this section discharges the product in form of a continuous ribbon. The capacity of such machines goes from 200 to 10 000 L/h.

The *Alfa process* (named after Alfa Laval, today Tetra Pak, Sweden), also called the concentration process, uses a hermetically closed centrifugal separator to concentrate pasteurized cream with 30 – 40 % fat to a fat content of 82 % (close to the fat content of butter). The resulting concentrated oil-in-water emulsion is then cooled and sheared in a cooling screw to achieve phase inversion. As no buttermilk must be removed from the churned product, the MFGM material becomes part of the butter. Butters produced according to this concentration process therefore have an increased phospholipid content. Another characteristic feature of butter produced by the Alfa process is the virtual absence of air in the product, while butters produced according to modified Fritz type processes contain 3 – 6 % of air.

Another technical variant widely used in the United States, is the *Cherry Burrel process*. This procedure also uses concentrated cream and a homogenizing device to destabilize the fat globule and induce phase inversion.

Packaging and Storage. Automated packaging of the finished butter should immediately follow its production, in order to avoid contamination with environmental airborne microorganisms and texture damage.

Packaging material for butter must provide light protection, be fat impermeable and oxygen-tight, in order to provide sufficient refrigerated shelf life of the product. The packaging material must be devoid of migrating metal ions and it must not adsorb and transmit odors from the environment.

Common packaging materials are parchment paper and aluminum foil with coatings on the product side.

Refrigerated shelf life for butter at 4 – 6 °C is about 4 weeks. For longer storage periods, butter can be stored frozen at − 25 °C.

Butter Defects. *Odor and flavor defects* of butter may originate from deficient cream quality or may be the result of the buttermaking process itself. Oxidative defects can result from in-

Figure 13. Continuous buttermaking plant (reproduced from [4] with permission)

creased copper or iron contents of the cream or from contaminated process water. To avoid lipolysis, adequate cream pasteurization is critical as it ensures inactivation of the lipases from microbial origin.

Texture defects in butter in finished butter with completed fat crystallization may result during its mechanical handling. If mechanical treatment leads to the coalescence of finely dispersed water droplets, water leakage can occur at a later moment. Coalesced interstitial water also favors bacterial growth in the stored product.

9.7. Anhydrous Milk Fat and Butter Oil [4]

Definitions and Properties. According to IDF Standard 68/1977 [136], *anhydrous milk fat* (AMF) must have 99.8 % fat at the minimum. Other quality criteria are the peroxide value, which has to be ≤ 0.2 meq/kg; and the free fat acidity which must not exceed 0.3 % (expressed as olein). The peroxide value is a measure for reactive lipid hydroperoxide intermediates; the free fat acidity is related to the extent of lipolytic deterioration. The latter can be determined by titrating the extracted fat with a weak alkali. Anhydrous milk fat must be produced either from butter or from fresh cream.

Butter oil is liquid milk fat with a minimum fat content of 99.3 %. While, according to the same IDF standard of identity, butter oil may contain up to 0.5 % moisture, AMF must have a maximum moisture content of 0.1 %. Anhydrous milk fat is solid at temperatures below 16 °C and has, if stored under N_2 gas at 4 – 6 °C, a shelf life of several months. It is a more suitable form of milk fat for transport and storage than butter. Major importers of AFM are nondairy countries that utilize AMF for recombining. Anhydrous milk fat and butter oil function also as raw materials for chocolate production, for the bakery, confectionery, and the ice cream industry.

Production [137]. Anhydrous milk fat is produced either from butter or from fresh cream. If *sweet cream butter* is the raw material, the butter is melted and warmed to 60 °C, and it is hold for some time at this temperature. From the holding tank the butter oil is concentrated in a centrifugal concentrator which separates the light butter oil phase from the heavier aqueous emulsion. The oil is then heated to >90 °C and residual moisture is stripped off in a vacuum chamber, up to a residual level of 0.1 % or less. When the raw material is *fresh cream*, the first step is concentration of the cream to at least 75 % fat in a centrifugal separator. The concentrate is then passed through a homogenizer at a high pressure, in order to induce phase inversion. Following this churning process, another concentration step is needed to bring the fat content to ca. 99.5 %. Heating at 95 – 98 °C and vacuum stripping of residual moisture will lead to the anhydrous product. After vacuum "drying", the oil is cooled to packaging temperature ($\approx$ 40 °C) and filled into containers or drums. The containers are first gassed with N_2, which sinks to the bottom because of its higher density as compared to oxygen. Upon filling of the liquid milk fat, the gas overlays the fat in the package. The packaging material has to be air tight and light proof.

Fractionation of Milk Fat [138 – 140]. At 28 °C melted milk fat can be separated by selective crystallization into a hard *stearin fraction* (melting range 40 – 45 °C) and a soft *olein fraction* (melting range 26 – 28 °C).

A semicontinuous process was developed in Belgium by A. Tirtiaux in 1976, which allows to separate sequentially crystallized triglycerides on a stainless steel vacuum belt filter. Milk fat fractions with different melting ranges can be produced by the Tirtiaux process. Such fractions are produced to satisfy specific requirements of the food industry. Main European producer of such tailor-made milk fat fractions is Corman in Belgium. Outside Europe, New Zealand Dairy Board has developed a continuous process for a spreadable butter, based on blending of milk fat fractions with different melting behavior.

Cholesterol reduction is another reason for refining butter oil or AMF. Several procedures lead to a reduction of the cholesterol content of the milk fat by about 90 % [139].

Mixing of the oil with powdered or granulated charcoal can remove up to 90 % of the cholesterol by adsorption. The adsorbent also removes color and flavor components from the

milk fat, these may have to be reintroduced after cholesterol removal.

In the *cyclodextrin* procedure inclusion complexes are formed between cholesterol and cyclodextrin, which can be precipitated from the oil phase. This procedure is less efficient than adsorption by carbon particles.

More recently, *supercritical CO_2 extraction* has become applicable to remove cholesterol. Up to 90 % of the total milk fat cholesterol can be removed using this procedure.

9.8. Dairy Spreads [141]

In the last two decades, numerous dairy spreads appeared on the markets in Western Europe and the United States. These spreads differ in their total fat level and in their proportions of butterfat to nondairy fat. Legislation regarding these products varies from country to country. Main raw materials for the manufacture of *pure dairy spreads* are butter oil, AMF and low-melting milk fat fractions. In the manufacture of *mixed dairy* spreads, vegetable oils, e.g., soybean oil or rapeseed oil, are mixed with milk fat in adequate proportions to obtain good spreadability at refrigeration temperature. In the production of *reduced-fat spreads*, often further components such as milk proteins, gelatin, modified starch, or carboxymethyl cellulose are needed to improve product stability and water immobilization.

Mixed spreads with a high fat content but improved spreadability have been on the market for some time.

Bregott is the name of a Swedish product with a total fat content of 80 % of which 15 – 30 % is soybean oil. The exact proportion of vegetable oil varies and is adapted to the (seasonal) hardness of the milk fat. Bregott has, at refrigeration temperature, better spreadability than butter, however it becomes too liquid at room temperature. Bregott has been on the market since the early 1970s.

Clover is a similar mixed spread developed in the United Kingdom and marketed since 1983. In this spread, hydrogenated vegetable oil is used, which makes the product less liquid at ambient temperature.

Reduced- or low-fat spreads have total fat contents $< 60\,\%$ (*reduced-fat spreads*) or $< 39\,\%$ for *low-fat spreads*. Spreads with fat contents of 39 – 41 % are also called *half-fat spreads*. Corresponding water-in-oil emulsions are produced, by dosing the aqueous phase (e.g., buttermilk) into the liquid fat phase. High shear devices such as scraped surface coolers or special homogenizers are needed to finely disperse the aqueous phase in the oil phase. The increased amount of dispersed water causes a sensation of empty mouthfeel and poor palatability. Addition of a small amount of milk proteins or gelatin improves the situation. The large amount of water also leads to microbial instability, thus the use of preservatives such as potassium sorbate or others is required.

9.9. Dairy Desserts [97]

This section only describes industry-made, ready-to-eat, or powdered desserts produced from milk, cream, and other milk constituents. Frozen desserts such as ice cream and frozen yogurt are dealt with in (→ Ice Cream and Frozen Desserts).

Ready-to-eat Desserts. Main categories of ready-to-eat dairy desserts include:

Puddings (Custards, Flans). These are mostly firmly textured, demoldable gels which are easily removable from their container. Typical examples are vanilla, chocolate, or caramel puddings with a caramel covering. Egg custards are mainly based on egg solids but most recipes contain significant proportions of milk SNF and cream. In dairy puddings, gelling is induced alternatively by heat setting (for whey protein and egg protein as well as for starch-based gels), by acid setting (for casein-based gels) or, as in the case of fresh curd products, by rennet-induced gelling of the dessert composition. It is also possible to create the gelled texture during a cooling step of the product, if gelatin or carrageenans are being used.

Creamy desserts include a wide variety of canned custards and liquid puddings. In contrast to custards or flans, these products are more or less viscous liquids with a creamy texture.

Aerated desserts can be based on fresh cheese curd, on cream, or on milk proteins (caseinates, whey proteins). Foam stabilizers such as starches, carrageenans, gelatin, and emulsifiers are used in such foamed dessert products.

Acid dairy desserts include fresh curd products (curd formation by lactic fermentation), yogurt-based desserts, and milk containing fruit preparations. Their creation often involves the use of highly methoxylated pectins, capable of producing gels at low pH.

Multi-layer desserts are made of several layers including chocolate layers, vanilla cream layers, fruits or fruit extracts. An upper layer of whipped cream is very common to these products, most of which have to be kept under refrigerated conditions.

Ready-to-eat desserts can also be classified according to their shelf life and storage conditions, and related with it, the mode of heat treatment used for their production. *Pasteurized products* require refrigerated storage and have shelf life of a few days up to several weeks. Hot filling after pasteurization allows 3 – 4 weeks of refrigerated shelf life.

Canned, retorted products are produced in rotary autoclaves by retorting in the temperature range of 115 – 125 °C for several minutes. This technology is particularly suited to produce long-shelf-life puddings and crèmes in metal cans; an example is *Crème Stalden,* a product from Nestlé in Switzerland.

UHT-sterilized desserts have long shelf life at ambient temperature, like the retorted ones but the heating process is less damaging. UHT-sterilization must be linked with aseptic filling. Packages mostly consist of paperboard, polypropylene, or polystyrene.

Powdered Desserts. Shelf-stable dairy dessert compositions can be produced in powdered form by spray-drying the liquid composition, as well as by dry mixing dry ingredients.

Powdered dessert compositions based on milk powders and containing pre-cooked starches and other ingredients are on the market. After their reconstitution in water or milk these powders are further processed into the ready-to-eat product by the consumer.

10. Quality Control

An inventory of international adopted (IDF, ISO, AOAC) methods of analysis and sampling of milk and milk products has been issued by IDF [142].

Quality control is a process taking place at different levels, from the raw material (raw milk) to the packaged product and its distribution and retailing.

Quality features concern in a first line food safety (in terms of microbiological and toxicological risks, contaminant and residue levels). Other quality features concern composition, such as maximum or minimum values for water and nutrients. Finally, adequate packaging and storage must ascertain that the required quality is maintained during the entire shelf life of the product.

Quality Control of the Raw Material. Quality control of raw milk includes both permanent and periodic control of specific quality factors. For virtually any kind of industrial transformation of raw milk, basic parameters such as acidity (°SH), pH, water addition (freezing point), or absence of antibiotics are established. Frequent periodical controls concern composition (total solids, total protein, fat content by automated infrared analysis), bacteriological quality and somatic cell content.

A somewhat longer periodicity is applied for specific controls such as testing for *Brucellosis* (every 2 – 3 months) and other udder diseases.

In a survey by the IDF in 1998 [143] the practice of quality payment was compared for >30 different countries. Besides hygienic standards, the total protein and the fat content are used everywhere as criteria. Some countries in addition use the total solids non fat (SNF) content.

Quality Control in Processing. In the industrial transformation of milk, preventive control measures along the production line are of greatest importance. The concept of Hazard Analysis & Critical Control Point (HACCP) aims at the identification of safety hazards within the production line (process) and to suppress such hazards by adequate control. It is considered that this procedure best guarantees the safety of the final product.

Finished Products Control. Analytical control of finished products has to ascertain that the product complies with legal requirements and with declared nutrient contents. Sterility testing is important for shelf stable, liquid milk products such as retort or UHT-sterilized, fluid products.

11. Legislation

Milk and dairy products are regulated in specific chapters of the Food Legislation on a world level by the Codex Alimentarius, on regional levels such as the European Union, and on a national basis. Today, national governments are pushed to implement Codex rules into national legislation.

Also, e.g., European countries are in the process to "harmonize" their national regulations with current EU legislation.

Codex Legislation Relative to Milk and Dairy Products [144]. Of major importance in the international trade with milk products is the "Code of Principles concerning Milk and Milk Products". This code is presently adopted by more than 70 countries throughout the world. Chapters relevant for the dairy industry are the volumes 1 a "General Requirements", and volume 1 b: "Food Hygiene" [145]. Volume No 4 contains requirements for infant foods and milk-based infant formulas [146].

Table 21. Codex Alimentarius standards for specific milk products

Type of product	Standard	Codex reference
Fresh milk products	fermented milks	STAN 243-2003
	creams and prepared creams	STAN A-9
Preserved milk products	evaporated milks	STAN A-3
	sweetened condensed	STAN A-4
	milk and cream powders	STAN 207-1999
	whey powders	STAN A-15
	edible casein products	STAN A-18
Milk fat products	butter	STAN A-1
	butter oil	STAN A-2

In addition to these general Codex rules, some 15 individual Codex Standards concerning specific milk products (not including cheeses) have been issued (Table 21). The standards, although not all yet widely adopted in national legislation, are becoming increasingly important in the international trade with milk products. Objective of the standards is to define the identity of a product, and to provide composition data and data relevant for quality.

European Union Legislation. The EU issued a number of directives concerning the identity, the denomination of milk and milk products, and on the use of processing aids and food additives in such products.

Of particular importance are the directives no. 1898/87 [96] on the denomination of consumer milks, as well as the complementary directive 2597/97 [90] concerning consumer milks.

Proposed Directive C 231/20 [99] deals with evaporated, sweetened condensed milks, and powdered milks. The use of additives (others than colors and sweeteners) in evaporated or powdered milks and other milk products is regulated in Directive 95/2/EC [128].

12. Economic Aspects

World Milk Production [147]. Total world production of milk of different species has surpassed 500×10^6 t/a. Since 1987 annual production of *cow's milk* amounted to nearly 470×10^6 t/a. In a ten years' period, total milk production has moderately increased, while the number of dairy cows has, in the same period, significantly decreased.

While production in Western Europe is decreasing, that of North America, Australia and New Zealand was increasing. Also some Latin American countries such as Argentina and Brazil have markedly increased their milk production.

Another feature is the increase in buffalo milk production, mainly due to India, which lead to a share of $>10\,\%$ of the total world production in 1997 (Table 22). Production of milk from goat and sheep has remained stable at a level of about 10×10^6 t/a for goat's milk and 8×10^6 t/a for ewe's milk.

Industrial Transformation of Milk. Out of 470×10^6 t/a of cow's milk produced worldwide in 1997, ca. 60 % was processed in dairies. (This percentage, however, depends on whether

Table 22. World milk production by species [147, 160]

Species	Milk production, 10^6 t						Increase since 1992, %

production occurs in an industrialized or in a developing country. In industrialized countries >90 % of the production goes to the dairy processing plant, while the percentage can be very low in developing countries.) The remaining ca. 40 % of the milk production, not processed in dairies, are consumed as loose milk, are used by the nondairy food industry or go to animal feed.

Table 23 shows data for the quantities of industrially produced milk products during the period 1987 – 1997. The largest fraction of the milk intake leaves the dairies in form of consumer milks (pasteurized milks or others). Among the industrially transformed milk, cheese production is clearly the largest segment, followed by butter and butterfat produc-

tion. Milk powder production accounts for some 4×10^6 t/a.

Some of the largest private companies transforming milk into consumer products include: Nestlé (Switzerland), Dairy Farmers (USA), Unigate (UK), Danone, Besnier, Bongrain (all France), Friesland Coberco, Campina Melkunie (both Netherlands), MD Foods (Denmark), Parmalat (Italy), Snowbrand, Meiji and Morinaga (all three Japan).

The milk price paid to milk producers in 1997 varied from \$ 0.2 to \$ 0.6 per kilogram of whole milk, depending on country, an EU average being ca. \$ 0.35 per kilogram.

International Trade [148]. Shelf-stable milk products such as skim milk powders, whole milk powders, butter powders and other powdered products are exported into nondairy countries or countries with insufficient own milk production for the production of dairy products by recombining, as well as for other uses in the food industry. Other very important export products are cheeses and milk fat in form of AMF or butter oil. Data about exporting and importing countries for milk powders and butterfat are shown in Tables 24–26. Besides the EU, New Zealand and Australia are the major exporting countries in the world.

Consumption of Milk Products. Consumption data for 1996 (Table 27) illustrate the per capita consumption of liquid milk and major milk products in various regions of the

Table 27. Consumption of dairy products in 1996 [149]

	1996 per capita annual consumption, kg							
Product	EC (15)	U.S.A.	Mexico	Brazil	Argentina	Australia	New Zealand	Japan
Liquid milks total	75.1	101.8	54.9	72.4	57.4	108.1	91.9	40.2
Fermented milks	21.6	7.2	1.6		6.3	5.2		14.2
Cream (as butterfat equiv.)	3.5	3.7			0.5			0.5
Butter	4.5	2	0.3	0.5	1.4	3.2	8.1	
Cheese	16.3	13.7	4.5	2.6	10.9	3.2	9.2	
Total listed milk products	121	128.4	61.3	75.5	76.5	119.7	109.2	54.9

world. Since 1987, the consumption of liquid milk in industrialized countries such as the EU is stagnating, while that of fresh dairy products (yogurts, fresh cheeses and milk desserts) is increasing. Pasteurized milks lost market shares in favor of UHT milks and milk beverages.

On a world scale, consumption of butter remains roughly stabile, while that of cream shows some increase. While butter consumption via retail trade may have decreased, this loss was compensated by increased industrial consumption. Positive developments are seen for fresh dairy products and for cheese. Milk products consumption shows highest growth rates mainly in East and South Asia (4 – 5 % growth per year). There are also growing markets in Latin America.

1. History and Definitions

Mirrors provide humans with a unique ability to control and direct light by reflection from a surface. In this article, the development and function of mirrors will be described.

Cosmetic and General-Use Mirrors. Low-cost mirrors such as those used in home furnishings and automobiles are known as *second surface mirrors.* They are produced by application of a chemical silvering agent or evaporating a reflective coating (usually aluminum) on the surface of large sheets of flat glass (Chap. 5). The mirrors are then cut using diamond scribes. The glass is mounted with the coated surface to the back so that the coating comes from the back or second surface. These mirrors perform acceptably, although the clarity of the reflected image is reduced by reflections from the first glass surface. These reflections account for ca. 4 % of the incoming light compared to about 90 % from the coated surface.

A *first surface mirror* has the reflective coating on the outer or first surface of the glass substrate. Such mirrors are used where higher accuracy is demanded. Since all the reflection comes from this surface, only a single image is formed resulting in excellent clarity.

Flat mirrors simply reflect the rays of light arriving at their surface without changing their relative directions. *Curved mirrors* can be used to focus, spread, or collimate a bundle of rays. They are used in imaging systems ranging from flashlight reflectors to lasers to large telescopes. Substrates for curved mirrors may be glass, metal, or plastic. Whereas glass mirrors can be sagged to shape, metal and plastic mirrors are produced by depositing the substrate materials on a curved master, then coating with a highly reflective material. Designs often include a housing to protect the coated surface from contamination and damage.

Laser Mirrors. The development of lasers and laser optics has increased standards for high-quality finishing and coating. Ring laser gyros demand surface roughnesses of 0.1 – 0.2 nm and multilayer dielectric coatings producing reflectivities > 99 %. These mirrors measure only about 5 mm in diameter and are machined from a solid disk of β-quartz glass ceramic. Their supporting structure is optically contacted to the laser frame and the surface is activated by piezoelectric controls.

Scattering from the surface of laser mirrors is a particular problem, since the laser must maintain a very stable standing wave. This places special demands on the procedures used in grinding and polishing to eliminate subsurface fractures. Coatings must be very uniform and designed to withstand the high heat load generated by the laser.

Mirrors in Astronomy. The most spectacular advances in mirror design have come from the most demanding of mirror users, the astronomers. The art and science of producing mirrors was revolutionized with the invention of the reflecting telescope by Sir Isaac Newton in 1668. Previously, all telescopes were refracting, i.e., they used glass lenses and prisms to collect and focus light. These had serious limitations because of the mass of the lenses, the great length of the tube required, chromatic aberration (inability to focus all wavelengths at a single point)

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a16_641

and the need for high-purity, low-distortion optical glass.

NEWTON's invention addressed two needs of astronomers that are still important today: (1) high light gathering power and (2) low distortion of the arriving light wave by the optical apparatus and the surrounding atmosphere. Great light gathering power is needed to collect the faint light from a distant object and is achieved by using large-diameter primary mirrors, high-reflectivity coatings, and sensitive detectors. Low distortion of the light wave is needed to achieve high image resolution. The full aperture of the primary mirror must maintain a precise curved shape, even under thermal variations. The compactness and practical execution of NEWTON's design allowed the apparatus to be located on remote mountain peaks, well above disturbances of the atmosphere.

The eighteenth century (1789) saw the production of the first large (48-inch) metal telescope mirror in England under the direction of WILLIAM HERSCHEL. This mirror weighed ca. 1000 kg and was contained in a tube 12 m long. It proved to be difficult to use because it contained no tracking mechanism.

Development of Glass Mirrors. The major disadvantage of metal mirrors was their tendency to distort with temperature due to a relatively large thermal expansion coefficient. Silicate glass has a much lower thermal expansion coefficient and can be polished to higher finishes than metals, but it does not have a high reflectivity. The invention of the silver coating of glass by reduction of silver nitrate revolutionized the design of mirrors. This process was credited to KARL STEINHEIL, a German physicist, in 1856. In 1857 the French physicist FOUCAULT independently announced his invention of a process for figuring (grinding to shape) and coating with a silver solution. Major advances in the technology of telescope mirrors are summarized in Table 1.

Parts of a Mirror. Figure 1 illustrates the parts of a lightweight mirror. The concave *faceplate* supports the reflective coating. The faceplate is bonded to a lightweight glass *core* to increase the stiffness. The core is mounted on a glass *backplate*. The faceplate is ground to a spherical or paraboloidal shape and focuses light from an infinite object at the focal length f, which is related to the radius of curvature R by $f = R/2$. A *spherical shape* is easier to obtain by standard grinding techniques, but forms an accurate image only at small angles where the spherical surface closely approximates a paraboloid (the paraxial region). This means that the mirror will be relatively flat and that long focal lengths are needed.

Figure 1. Lightweight mirror design
a) Concave faceplate; b) Lightweight fused-strut core; c) Planar backplateA spherical mirror focuses rays of incoming parallel light at point F which is at a distance one half the radius of curvature, R.

A *paraboloidal shape* forms much sharper images because rays from all points of the mirror focus sharply to the same point. Paraboloidal mirrors are, however, more difficult to produce because the radius of curvature is different for each point on the mirror.

The core is composed of cast or fused struts of material with the same thermal expansion as the faceplate. The backplate may be flat or curved, it provides the reaction surface to carry the load of the faceplate and core as well as the mounting points for joining the mirror to the mounting structure. In an *active mirror*, the core is replaced by a network of actuators which constantly monitor and adjust the surface of the mirror.

2. Substrate Materials and Forming Techniques

2.1. Materials

The mirror substrate material must meet two primary requirements. Firstly, its mechanical and

Table 1. Milestones in the development of telescope mirrors

Mirror	Material ∗	Size, m	Significant technology
NEWTON's mirror	metal	0.1	first reflector telescope, 1668
HERSCHEL's mirror	metal	1.2	first large mirror, 1789

∗ Pyrex, ULE, and Zerodur are registered trade marks; ULE = ultralow expansion.

thermal properties must ensure minimum distortion from external influences. These properties must be homogeneous throughout the mirror body and constant over the expected service life of the mirror. Glass and glass ceramics provide excellent stiffness and display elastic behavior over their entire stress range. Secondly, the materials must be capable of being polished to a surface roughness measured in tenths of nanometers and be capable of accepting and holding an evaporated reflective surface. Single-phase optical glass is ideal for this because it is homogeneous and can be heated to several hundred degrees Celsius for coating. Glass ceramics can also be polished to a high finish provided that the residual glass component has similar mechanical and chemical characteristics to the crystalline phase.

Thermal and mechanical properties of some common mirror substrate materials are shown in Table 2.

Borosilicate Glass (→ Glass, Chap. 2.2.4.). Borosilicate glass (Pyrex) was invented in the early 1900s for use in railroad lamps. Its low thermal expansion prevented breakage when rain splashed on the hot surface of the glass. It is a relatively difficult glass to form when compared to soda lime compositions (window glass), but proper compositions resist devitrification (crystallization) or phase separation. Borosilicate glass is relatively easy to finish and is inexpensive. Because of its high thermal expansion, it is used in instrument mirrors that do not require high precision.

Silica Glass (→ Glass, Chap. 2.2.1.). Silica glass is pure SiO_2 and is referred to as fused silica, vitreous silica, fused quartz, or just quartz. It may be produced by melting natural quartz crystals or beach sand, but the very best optical-quality glass is produced by vapor phase deposition in which $SiCl_4$ gas is oxidized in a high-temperature burner and deposited on a substrate. Mirror materials are cut from these large boules of very pure glass.

Silica glass is usually the material of choice for infrared mirrors because its thermal expansion is very low under cryogenic conditions. Because of its simple formula and amorphous structure, its thermal expansion is very consistent and predictable.

ULE Glass. Ultralow expansion glass (ULE) was invented in the early 1940s when researchers at Corning found that substituting about 7.5 wt % TiO_2 into SiO_2 reduced the thermal expansion from 0.5 to $< 0.03 \times 10^{-6}\,K^{-1}$. Due to its high viscosity, it must also be synthesized by vapor phase deposition. This process allows very precise control of the composition, and hence the thermal expansion coefficient.

The thermal expansion and the elastic modulus are both correlated to the titania content. The thermal expansion of the material can be measured nondestructively at any location in the boule by measuring the speed of sound. Boules may therefore be selected and matched for thermal expansion in very critical applications.

Glass Ceramics. Glass ceramics are materials which can be formed using conventional glass-forming technologies such as casting,

Table 2. Mechanical and thermal properties of some common mirror materials

Material	Thermal expansion coefficient (25 °C), 10^{-6} K	Elastic modulus, GPa	Thermal conductivity, $W\,m^{-1}\,K^{-1}$
Titanium silicate glass (ULE)	0.00 ± 0.03	67.6	1.3
LAS glass ceramic (Corning 9600)	− 0.01	95.3	1.5
LAS glass ceramic (Zerodur)	− 0.03	91.0	1.6
Silica glass (Corning 7940)	0.52	73.1	1.3
Borosilicate glass (Pyrex, Corning 7740)	3.2	62.7	1.1
Molybdenum	5.0	324	146
Beryllium	11.5	303	182
Nickel	15.3	204	74.9
Aluminum	23.4	68.9	222

blowing, or pressing, but are then reheated and crystallized to yield a low thermal expansion, highly crystalline body (→ Glass Ceramics).

Schott Glaswerke (Mainz, FRG) has extensively developed β-quartz glass ceramics (Zerodur) for telescope mirrors. This required solving the vexing problem of how to limit the stress induced by volume change during crystallization. Very long crystallization cycles and retention of a phosphorous-rich residual glass phase has permitted crystallization of spun-cast plates up to 4 m in diameter.

Glass ceramics are particularly well suited for ring laser gyro mirrors where low thermal expansion, transparency, and impermeability to helium are of paramount importance. Corning Code 9600 has been optimized for this application by reducing the thermal expansion to under $0.01 \times 10^{-6}\,K^{-1}$. Its very small crystal size results in low scattering and permits polishing to less than 0.1 nm root mean square surface roughness.

Metals and Composites. The development of glass mirrors practically eliminated the use of metal mirrors in precision telescope applications. Nevertheless, metal mirrors continue to be used in parabolic reflectors and in high-energy laser mirrors which require cooling. Nickel is used in many parabolic reflectors because it can be chemically deposited on a master form. Once deposition is complete, the thick layer of nickel is removed intact from the master resulting in a finished mirror which replicates the shape of the master form. Molybdenum has been used extensively for high-energy mirrors, but beryllium is becoming increasingly popular because of its low density and high thermal conductivity. A disadvantage of beryllium is its high toxicity which demands special machining precautions.

Aluminum reinforced with silicon carbide whiskers shows some promise for mirrors; the whiskers increase the modulus of elasticity and reduce thermal expansion. Carbon fibers have near-zero thermal expansion, excellent thermal conductivity, and very high mechanical stiffness. These fibers may be combined with epoxy, glass, or glass ceramic matrices to produce high-strength, high-toughness composite mirror substrates with very low thermal expansion. Although the composite material cannot be polished well enough to produce a high-quality surface, polishable surface materials can be applied as laminates. For example, ULE or silica glass faceplates can be bonded to a composite back structure.

2.2. Forming Techniques

Monolithic Casting and Hex Fusion. *Monolithic casting* is rarely used now for large mirrors. It involves directly filling a mold made from refractory bricks with molten glass by ladling or by tapping a glass tank. The glass must then be cooled quickly enough to avoid

devitrification, reheated to the annealing temperature, and very slowly cooled to eliminate thermal stress. If a glass ceramic is used, the annealed glass must be crystallized in a high-temperature thermal cycle to develop the desired low expansion phase. Schott has used centrifugal casting to produce 4-m meniscus blanks and plans a similar approach for the 8-m blanks for the European Southern Observatory.

Hex fusion was developed for large silica glass or ULE castings that cannot be poured or ladled into a mold. Small (ca. 1 m diameter) boules are cut into hexagonal tiles and carefully fitted together in a mold. The glass is heated and fuses together into a large mass. This approach has the advantage that each boule can be inspected before it is committed to the mirror blank.

Lightweight Centrifugal Casting. The Stewart Observatory (University of Arizona) has pioneered the technique of centrifugal casting of structured mirrors. A mold is constructed using low-density fibrous refractory blocks with the areas which will become ribs appearing as narrow gaps between the blocks. A gap between the mold back and the blocks also allows glass to flow under the blocks forming the backplate.

Borosilicate glass cullet (first-sized broken blocks) is loaded into the cold mold. Heat is applied and when the glass begins to soften, the entire apparatus is spun at about 8 rpm. Spinning causes the surface of the glass to assume a parabolic shape. Once the glass cools below the settling temperature, spinning is stopped. Residual stresses are annealed out of the glass blank by very slow cooling.

The Stewart group has also reported success in spinning 0.5 m disks of Corning Code 9600 glass ceramic; this approach could combine the advantages of a low thermal mass design and a low expansion material.

Ultralightweight Frit Bonding. This approach constructs the lightweight core by welding together thin slabs of precut ULE glass. The frit, a powdered glass ceramic designed to match the thermal expansion of ULE, is suspended in an organic vehicle and applied to the ends of the core struts. The faceplate and backplate are then placed on the core and the entire structure is heated to the sintering temperature of the frit. The frit forms a fillet weld between the core and front and back surfaces and is stronger than the ground glass itself.

Frit-bonded mirrors are attractive for space-based instruments where launch weight is critical. The mirror can be built up step by step and inspected at each critical juncture.

3. Grinding and Polishing

Grinding. After the blank has been produced and annealed, it is placed on a machine which grinds the surface into the desired radius of curvature. The grinding tool typically consists of fixed abrasives such as diamond or silicon carbide buttons on a metal surface which has been machined to the same radius of curvature as the mirror.

Grinding must be performed very slowly to avoid damaging the glass surface and may require months or years for a very large mirror. Since heat can distort the grinding tool, grinding is often carried out in temperature-stabilized environments.

Very high thermal "spikes" can occur at locations where the diamond cuts the substrate. This can lead to thin layers of stressed glass on the ground surface which must be removed by an acid etch treatment.

Polishing. The ground, shaped mirror blank is moved to a polishing machine. Starting with coarse grits, the blank is moved through progressively finer grinding materials. Typical polishing materials include diamond, silicon carbide, aluminum oxide, and cerium oxide for the final polish. They are either suspended in a liquid that is applied to the surface or contained on fabric tool surfaces.

During finishing, the optician must often check the surface curvature or *figure* of the mirror with an interferometer to ensure that it corresponds to the desired spherical or parabolic shape. The final quality of the mirror is usually determined by this deviation from the ideal figure. High-quality optics have deviations of less than a tenth of the wavelength of light across their aperture.

Parabolic shapes are particularly desirable for very large aperture telescope mirrors since they can reduce the focal length of the mirror. These

so-called "fast" mirrors require very special polishing tools and techniques because the lap (polishing tool) must fit the surface of the mirror to within about 3 µm, but the radius of curvature is different for each point on the mirror's radius. To solve this, the Stewart Observatory Mirror Laboratory is developing deformable laps which can change their radius of curvature on each stroke. Itek is stressing the mirror during polishing for the segments of the Keck parabola. The European Southern Observatory's 3.8 m New Technology Telescope has employed a pressure-controlled lap.

4. Coatings

The role of the massive glass faceplate and support structure, actuators, and mounting apparatus is to support the few grams of coating material where photons of light are reflected.

Coatings are usually applied by *vacuum deposition*. The entire mirror substrate is first scrupulously cleaned to guarantee adhesion of the coating. It is then placed in a vacuum chamber and the coating is applied by heating a metal or oxide target with an electron beam to deposit a thickness of a few hundred nanometers on the substrate surface. During use, coatings may tarnish or become scratched. Most metal coatings can be stripped using acids and a fresh surface can be applied.

Metal Coatings. Metals are the standard coatings for mirrors because of their high reflectivity and ease of application. The preferred metal coating for applications in the visible and near infrared is aluminum. Although it does not have the reflectivity of silver, aluminum is less prone to tarnishing. Fresh aluminum coatings provide reflectivities of about 90 % over most of the visible whereas silver may be as high as 98 %. Additional layers of dielectric materials (e.g., MgF_2) may be used to enhance reflectivity over a specific wavelength range and for protection against oxidation.

Silver provides the highest reflectivity, but is very prone to tarnishing. It is most often used on mirrors which provide internal reflection, e.g., on the faces of glass prisms. In this application they can be protected with overcoats of other metals such as copper to prevent oxidation.

Gold coatings are preferred for infrared mirrors because of their excellent tarnishing resistance and very high reflectance (96 to > 99 % for wavelengths of 0.7 to 5.0 µm). Their use is limited to controlled clean environments because they are prone to scratching and difficult to clean. Rhodium coatings are often used with electrodeposited nickel parabolic reflectors. They provide about 80 % reflectivity, but are very resistant to tarnishing, even in salt water.

Dielectric Coatings. Performance can be enhanced by using multiple layers of dielectric materials (e.g., SiO_2, TiO_2, MgF_2, and Al_2O_3) that are arranged so that as the incident beam moves from one layer to the next, part of it is reflected exactly in phase with the reflection from the previous surface. These coatings require precise control of the deposition chamber and typically operate over a limited wavelength and incident angle range, but have excellent reflectivity (> 99 %) and high durability and tarnish resistance. Coatings can also be designed to reflect certain wavelength ranges and transmit others. For example, the reflector in the lamp used in a dentist's office uses a "cold" mirror that reflects most of the visible but transmits most of the infrared. This is reversed for a "hot" mirror which reflects the infrared radiation and transmits the visible. A coating of this type is used on the windows of the Space Shuttle to reduce solar infrared heating.

5. Production of General-Purpose Mirrors

Production of general-purpose mirrors comprises four main stages

1) Cleaning of the glass surface
2) Sensitization of the glass surface
3) Formation of a silver layer
4) Application of a protective coating on the silver layer

Industrial mirror production is performed in units equipped with conveyor belts having a width of 1 – 3.4 m and a length of 50 – > 200 m (Fig. 2). The belt speed is 1 – 10 m/min. The reagents used to produce the silver and protective copper coatings are sprayed onto the glass.

Figure 2. Large-scale production of mirrors
a) Polishing brushes; b) Washing brushes; c) Water wash; d) Stannous chloride; e) Silver nitrate – dextrose solution; f) Copper sulfate solution, zinc dust; g) Drying; h) Application of base lacquer coat; i) Application of top lacquer coat; j) Evaporation; k) Cooling; l) Cleaning

Cleaning is performed with rotating brushes and/or rotating or oscillating polishing felts with polishing agents. The glass is subsequently washed.

Sensitization. The glass surface is sensitized with a stannous chloride solution to ensure uniform adhesion of the silver precipitate. Excess stannous chloride is washed off because it would interfere with the silvering process.

Silvering. Silver is precipitated by reducing an ammoniacal silver nitrate solution with agents such as dextrose, hydrazine, formaldehyde, tartaric acid, or gluconic acid. The glass is then washed again.

Application of Protective Coating. The protective coating consists of a layer of copper and one or two coats of lacquer. The copper is applied on top of the silver either by chemical reduction of copper(II) ions to copper(I) ions or by a contact process. In contact coppering a nonnoble metal (zinc) powder is sprayed onto the mirror together with an acidic copper sulfate solution. The copper(II) ions are precipitated by the metal powder. After application of the lacquer by pouring, rolling, or spraying, the mirror is subsequently dried, cooled, cleaned, and stacked.

5. References 7

1. Introduction

Molluscicides are agents employed to control gastropods. Gastropods form the class containing the most species in the phylum Mollusca. The pulmonate gastropods (Pulmonata, Stylommatophora) feed on plants and are mainly responsible for damage in horticulture, agriculture, and crop storage; they also spread infectious plant diseases, spoilage bacteria, and cause contamination [1–6]. The importance of the aquatic pulmonates (Pulmonata, Basommatophora) lies in their role as intermediate hosts for pathological human and animal parasites [7], [8]. Control of the two groups of molluscs is based on their respective habits and often requires the use of different control agents or measures.

2. Agents for the Control of Slugs and Snails in Agriculture and Horticulture

Damage caused by gastropods has increased as a result of modern methods of cultivation. Reduced mechanical cultivation of the soil improves their chance of survival. Gastropods represent a serious problem in crops such as potatoes or transplanted vegetables which are grown at low plant densities. The loss of even a single plant per meter of row can result in significant stand and yield reductions. Other crops which are especially prone to attack (particularly in the seedling stage of growth) are cereals, rape, legumes, and ornamental plants. In plants intended for canning or deep freezing (e.g., vegetables and strawberries), soiling with slime and excreta is a particularly serious problem.

The damage done by slugs is particularly serious, especially that caused by the common slugs (*Deroceras agreste* L. and *D. reticulatum* Müll.) which are found worldwide in regions with a temperate humid climate. Under mild conditions they are active and capable of reproducing throughout the year; like all pulmonates they are hermaphrodites. The slug species *Arion hortensis* Fér., *A. ater* (L.), *A. circumscriptus* Johnst., and *Milax budapestensis* Hazay are all increasing in importance. The latter species lives underground and is penetrating more and more into southern Europe, causing damage primarily in green-houses.

Snails are better adapted than slugs for surviving dry periods and are therefore also very important in warmer regions. Important species in the Mediterranean region include the Mediterranean sand snail (*Theba pisana* Müll.) in citrus groves and the European edible snail (*Helix aspersa* Müll.), which has also been introduced into the United States. The giant African snail (*Achatina fulica* Bowdich) has colonized many countries and is also of great importance [3].

Since the introduction of direct sowing in aqueous rice cultivation, aquatic snails belonging to the operculate group (Prosobranchia) have caused problems in many countries. These snails possess a double breathing system consisting of gills and a breathing tube (see Chap. 3 for the control of these water snails). The "golden apple snail", *Pomacea* sp. (*Ampullaris*) was introduced into Taiwan from Central America at the start of the 1980s and has developed into a sig-

10.1002/14356007.a16_649

nificant pest in rice fields [9] ; it is now spreading rapidly throughout the Philippines [10].

In contrast to the large number of insecticides, only a few chemical agents are available for the control of terrestrial gastropods.

Corrosive and Dehydrating Agents. Corrosive and dehydrating agents were employed initially for the control of terrestrial slugs and snails, slugs being particularly sensitive. High water loss as a result of extremely high slime excretion paralyzes the animal and leads to death. Quicklime CaO, freshly slaked lime $Ca(OH)_2$, and finely ground kainite $KMg(Cl/SO_4) \cdot 3\,H_2O$ are effective when applied in dry weather at a concentration of 300 – 600 kg/ha. The slugs or snails must, however, come in direct contact with these chemicals and be treated twice within a short period of time. The best results are obtained when the compounds are applied early in the morning or in the evening at the time of greatest gastropod activity. However, because of the potential crop damage from such treatments, it is recommended that these applications be made before the crop plants emerge above the soil. Rainfall rapidly inactivates these corrosive agents, as well as soluble agents such as copper sulfate (see below) and physical barriers such as sand, ash, soot, and cattle salt. Protective strips of fine sand, ash, and soot have an indirect drying effect due to the fact that the fine particles adhere to the moist foot and body of the slug or snail. The animals are then unable to crawl on such substances and thus dry out in warm weather. Cattle salt dehydrates the gastropods. Protective strips rapidly become ineffective in the presence of moisture and have to be reapplied at frequent intervals.

Copper(II) sulfate [*7758-99-8*], cupric sulfate, $CuH_{10}O_9S$, M_r 249.7, consists of blue crystals which are soluble in water, moderately soluble in methanol, and practically insoluble in most organic solvents (→ Copper Compounds, Chap. 4.4.1.[11, p. 270].

$CuSO_4 \cdot 5\,H_2O$

Copper sulfate is employed in considerable quantities against terrestrial gastropods, particularly in the developing countries. The compound is usually pulverized and applied at a concentration of 10 – 20 kg/ha; for ease of handling, it is often mixed with commercial fertilizer in a ratio of 1 – 2 : 40. Spraying with 12 kg of the agent dissolved in 400 L of water per hectare is also recommended. Because copper sulfate is a contact poison, snails and slugs must come into direct contact with the compound. Standing crops should not be treated in order to avoid damaging the plants.

Trade Names. Blue Viking (Griffin); Super Bouillie (La Cornubia); Triangle Brand (Phelps-Dodge).

Calcium cyanamide [*156-62-7*], $CaCN \cdot CN$ has been used as a repellent along the edges of fields to prevent the entry of slugs and snails.

Metaldehyde [*108-62-3*], 2,4,6,8-tetramethyl-1,3,5,7-tetroxocane, $C_8H_{16}O_4$, M_r 176.2, *mp* 246 °C, is the cyclic tetramer of acetaldehyde (→ Acetaldehyde, Chap. 8.2. It forms a crystalline powder which is moderately soluble in water, fairly soluble in toluene, and readily soluble in methanol [11, p. 796]. Metaldehyde is produced by polymerization of acetaldehyde in aqueous ethanol in the presence of HBr and alkaline-earth metal bromides [12].

The molluscicidal activity of metaldehyde has been exploited in South Africa since 1934 and was discovered independently in France in 1936 [13]. Ingestion of metaldehyde causes irreversible permeability of the gut walls of gastropods and leads to their death. However, under favorable weather conditions (low temperature, high relative humidity), gastropods often survive the paralysis produced on contact with the compound and the increased slime production caused by irritation. Metaldehyde is also effective in the vapor phase and kills gastropod eggs. Different species are affected to differing degrees.

Metaldehyde is usually applied in the form of pelletized bait based on wheat bran or barley flour containing 4 – 6 % of the agent. Despite the addition of various attractants (proteins, dextrose, casein, etc.), these baits are not often eaten

by purely herbivorous gastropods and act mainly as contact poisons; the bait should therefore always be spread evenly rather than in small heaps. In spite of their similar composition, the amounts of individual baits employed differ greatly, depending on the size of the bait particles. Pellet lengths range from 1 to 10 mm, but 2 – 5 mm is most common. If the bait is of good quality (high attractant power and stability during rainfall), 25 particles per square meter can guarantee adequate control for the most destructive gastropod species. Small bait particles (2 – 4 mm long, diameter ca. 2 mm) allow application of smaller quantities (3 – 9 kg/ha) without loss of efficacy [14].

Repellents, such as nonanoic acid vanillylamide are often added to discourage the consumption of slug bait by mammals [15].

Slug pellets containing metaldehyde are manufactured by many companies throughout the world. The official plant protection agent registers of Germany, for instance, list a large number of commercial preparations [16].

Metaldehyde can also be sprayed or dusted as a powder, but larger quantities are required (ca. 5 kg of active ingredient per hectare) than when it is employed in bait. Gastropods must come into direct contact with the spray or dust. A viscous paste containing 4 % metaldehyde is available. Drops of the paste are applied around the plants.

Trade Names. Cekumeta (Sequisa); Halizan (Tamogan); Hardy (Chiltem); Meta (Lonza); Metason (Jewin-Joffé); MifaSlug (FCC).

Methiocarb [*2032-65-7*], mercaptodimethur, 3,5-dimethyl-4-(methylthio)phenyl methylcarbamate, $C_{11}H_{15}NO_2S$, M_r 225.3, *mp* 119 °C, consists of colorless crystals which are sparingly soluble in water and hexane, and fairly soluble in dichloromethane, isopropyl alcohol, and toluene [11, p. 813].

Methiocarb is produced by the reaction of methyl isocyanate with 3,5-dimethyl-4-methylthiophenol, which in turn is prepared from 3,5-dimethylphenol and methyl sulfenyl chloride [17].

Methiocarb was first employed as an insecticide in 1962 and has been used as a molluscicide since 1964; it also possesses acaricidal acticity. Methiocarb is a molluscicide with neurotoxic action (cholinesterase inhibition) and is used to control slugs and snails in a wide range of agricultural situations. Like metaldehyde, methiocarb is employed almost exclusively in the form of bait at a concentration of 1, 2, or 4 %. Slug bait formulated as small pellets is generally applied in amounts of 3 – 5 kg/ha, corresponding to 20 pellets per square meter. As with metaldehyde, the amount of agent required increases considerably if spray application is employed (e.g., 0.5 – 1.75 kg of active ingredient per hectare); slugs and snails must also come into direct contact with the spray. Seed treatment with 0.1 – 0.2 % methiocarb is employed when sowing wheat to avoid damage by slugs.

Gastropods are rapidly paralyzed on feeding or contact; those affected do usually not recover [18]. The effect is largely independent of temperature and is particularly good under moist conditions.

Trade Names. Mesurol, Draza (Bayer).

Thiodicarb [*59669-26-0*], 3,7,9,13-tetramethyl-5,11-dioxa-2,8,14-trithia-4,7,9,12-tetra-azapentadeca-3,12-diene-6,10-dione, $C_{10}H_{18}N_4O_4S_3$, M_r 354.5, *mp* 173 – 174 °C, consists of colorless crystals which are sparingly soluble in water but readily soluble in dichloromethane, acetone, methanol, and xylene [11, p. 1195].

Thiodicarb is produced by reaction of *N*,*N*′-thiobis(methylcarbamic acid fluoride) with 2-methylthioacetaldoxime in the presence of a base [19].

Thiodicarb is a carbamate insecticide (cholinesterase inhibition) with molluscicidal properties. It was introduced in France in 1988. The recommended application rate for pelleted bait containing 4 % active ingredient is 5 kg/ha [20].

Trade Names. Skipper, Larvin (Rhône – Poulenc).

Fumigants are required for quarantine measures to prevent the introduction of gastropod pests from foreign countries. A mixture of 10 % ethylene oxide and 90 % carbon dioxide (ca. 320 g/m^3 for 72 h) is effective against snails even in their closed state (against *Achatina*), as are hydrogen cyanide (8 mg/L for 2 h under reduced pressure), and methyl bromide (ca. 130 g/m^3 for 72 h). Methyl bromide appears to be tolerated particularly well by plants when used in vacuum fumigation and allows the decontamination of imported seeds [21].

Insecticides and Fungicides. A range of carbamate insecticides also have molluscicidal activity. This is particularly true for Trimethacarb.

Trimethacarb [*12407-86-2*], mixture of 3,4,5- and 2,3,5-trimethylphenyl methylcarbamate (ratio: 3.5 : 1), $C_{11}H_{15}NO_2$, M_r 193.2, *mp* 105 – 114 °C, is a buff to brown crystalline product which is sparingly soluble in water and in organic solvents [11, p. 1254].

Trimethacarb is obtained by reaction of a mixture of 2,3,5- and 3,4,5-trimetylphenol with methyl isocyanate [22]. Trimethacarb is a cholinesterase inhibitor that is used to control a wide range of mollusc pests, and it also acts as a mammal and bird repellent.

Fentin Acetate [*900-95-8*], triphenyltin acetate, $C_{20}H_{18}O_2Sn$, M_r 409.0, *mp* 121 – 123 °C, consists of colorless crystals which are sparingly soluble in water, and fairly soluble in ethanol, ethyl acetate, hexane, dichloromethane, and toluene [11, p. 533].

Fentin acetate is produced by treatment of triphenyltin chloride with sodium acetate [23]. Fentin acetate is used for the control of algae and snails in rice fields, and also for the control of water snails in fish ponds.

Trade Names. Brestan (AgrEvo); Badar (Productos OSA); Suzu (Nihou Nohyaku).

Other Agents. Phosphate esters are active against gastropods only in exceptional cases. A good effect against slugs has been described for phorate (→ Insecticides). Azinphos-methyl (→ Insecticides) has been employed successfully for a considerable time against *Helix aspersa* in Californian citrus groves. Persistent molluscicidal activities have also been detected for nitrophenols (→ Insecticides, Chap. 4.) and for copper-containing fungicides (→ Fungicides, Chap. 6.1.) when employed for postharvest treatment in berry crops.

New Developments. The Rothamsted Experimental Station in the United Kingdom is working on the development of a new group of molluscicides. These are metal chelate complexes that contain iron or aluminum as the central atom [24].

3. Combating Gastropods as Parasite Hosts

Gastropods play an important role in human and veterinary medicine as hosts (vectors) in the life cycles of digenetic trematodes (flukes). In Europe, *Lymnaea truncatula* is the vector for the great liver fluke (*Fasciola hepatica*). In East Asia, *Fasciolopsis buski*, the "giant intestinal fluke" is spread by snails of the family Planorbidae (*Segmentina* species). *Dicrocoelium dendriticum*, the small liver fluke, requires pulmonate snails (e.g., *Helicella ericetorum, H. itala,* and *Zebrina detrita*) for its development. The life cycle of the Opisthorchidae trematode species (*Opisthorchis felineus, O. sinensis*) involves operculates belonging to the genus *Bithynia*.

According to the World Health Organization, about 200×10^6 people suffer from schistosomiasis (bilharziasis). In this context, several species of *Schistosoma* are of great importance

to humans in Africa, Central and South America, and East Asia [7]. *Schistosoma haematobium* (urinary schistosomiasis) and *S. mansoni* (intestinal schistosomiasis) require freshwater snails (*Bulinus* spp., *Biomphalaria* spp.) as hosts; *S. japonicum* (intestinal schistosomiasis) utilizes operculates (Prosobranchia *Oncomelania* spp.).

Successful control with molluscicides has been achieved only with schistosomiasis carriers. The agents and methods employed are, however, also applicable to the plant-damaging water snails discussed in Chapter 2. In the past, sodium pentachlorophenolate and copper sulfate were employed. Only one preparation is now available that can be judged as the agent of choice with regard to both its toxicology and its efficacy, this is niclosamide.

Niclosamide [*50-65-7*] 2',5-dichloro-4'-nitrosalicylanilide, $C_{13}H_8Cl_2N_2O_4$, M_r 327.1, *mp* 230 °C, consists of almost colorless crystals which are sparingly soluble in water but soluble in common organic solvents [11, p. 874].

Niclsoamide is produced by reaction of 2-chloro-4-nitroaniline with 2-hydroxy-5-nitrobenzyl chloride in the presence of a base [25].

Niclosamide is a molluscicide with respiratory and stomach action used to control golden apple snails in rice. Niclosamide is very effective against snails, snail eggs, and the free-living larval stages (miracidia and cercariae) of the schistosomes [26], [27]. It is also used for the control of schistosomiasis and fascioliasis in man by killing fresh-water snails which act as intermediate hosts, and for veterinary control of tapeworm infestations.

Niclosamide is available as a powder for sprays (70 %) and as an emulsion concentrate (25 %). The concentration applied to flowing and stagnant waters is 0.5 – 1 ppm for 8 h or 4 – 8 ppm for 1 h. Its biological effectiveness in water is stable at pH 5 – 9 and is also largely independent of the concentration of calcium and magnesium ions [28].

Niclosamide shows no phytotoxic effects on irrigated crops (e.g., bananas), it does not damage zoo- or phytoplankton. The compound does not accumulate in the food chain; it is biodegradable and metabolized by certain microorganisms. Niclosamide shows, however, lethal effects on fish at the concentrations in which it is applied.

Trade Name. Bayluscid (Bayer).

Trifenmorph [*1420-06-0*], *N*-tritylmorpholine, M_r 329.42, was formerly used against gastropods.

Older molluscicides, such as *yurimin* [*3281-96-7*], 3,5-dibromo-4-hydroxy-4′-nitroazobenzene, were employed in Japan against *Oncomelania hupensis nosophora*. Yurimin has a rather unfavorable acute toxicity. In addition, it is more toxic to fish than to gastropods. The product is no longer on the market.

Organotin compounds such as bis(tri-*n*-butyltin) oxide exhibit a molluscicidal effect, but because too little is known about their environmental behavior, work being done on these compounds may be discontinued [7].

Endod, a herbal extract of *Phytolacca dodecandra*, has been extensively investigated in Ethiopia [29]. It exhibits an adequate effect against *Biomphalaris pfeifferi*. Endod has only local importance; it is not available commercially.

4. Toxicology

Copper(II) sulfate [*7758-98-7*] [11, p. 270]

LD_{50} (rat, oral)	ca. 300 mg/kg
LD_{50} (mouse, oral)	87 mg/kg
NOEL/NOAEL:	
Chronic.	
Rat (2-year feed)	25 mg kg^{-1} d^{-1}

Metaldehyde [*108-62-3*] [30]

LD_{50} (rat, oral)	227 – 690	mg/kg
LD_{50} (mouse, oral)	200	mg/kg
LD_{50} (guinea pig, oral)	175 – 500	mg/kg
LD_{50} (rabbit, oral)	290 – 1250	mg/kg
LD_{50} (dog, oral)	100 – 1000	mg/kg
Nonteratogenic		
NOEL/NOAEL:		
Reproduction.		
Rat (3-generation feed)	10	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)
Chronic.		
Rat (2-year feed)	10	$mg\,kg^{-1}\,d^{-1}$

ADI: 0.025 $mg\,kg^{-1}\,d^{-1}$ [11, p. 796]

Methiocarb [*2032-65-7*] [31]

LD_{50} (rat, oral)	13 – 135	mg/kg
LD_{50} (guinea pig, oral)	14.1 – 100	mg/kg
LD_{50} (dog, oral)	10 – 25	mg/kg
LD_{50} (hen, oral)	175	mg/kg
LD_{50} (rat dermal)	> 300 to > 5000	mg/kg
LD_{50} (rabbit, dermal)	> 2000	mg/kg
LC_{50} (rat, 4-h inhalation)	> 0.322	mg/L air
Nonmutagenic		
NOEL/NOAEL:		
Reproduction.		
Rat (3-generation feed)	15	$mg\,kg^{-1}\,d^{-1}$
Teratogenicity.		
Rat (gavage)	3	$mg\,kg^{-1}\,d^{-1}$
Rabbit (gavage)	3	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)
Chronic.		
Rat (2-year feed)	1.3	$mg\,kg^{-1}\,d^{-1}$
Dog (2-year feed)	0.13	$mg\,kg^{-1}\,d^{-1}$

ADI: 0.001 $mg\,kg^{-1}\,d^{-1}$ [32]

Thiodicarb [*59669-26-0*] [33]

LD_{50} (rat, oral)	39 – 136	mg/kg
LD_{50} (mouse, oral)	226	mg/kg
LD_{50} (guinea pig, oral)	160	mg/kg
LD_{50} (rabbit, oral)	> 400	mg/kg
LD_{50} (chicken, oral)	582 – 660	mg/kg
LD_{50} (monkey, oral)	467	mg/kg
LD_{50} (rat, dermal)	2540	mg/kg
LD_{50} (rabbit, dermal)	> 6310	mg/g
LC_{50} (rat, 4-h inhalation)	0.1155 – 0.220	mg/L air
Rabbit: nonirritating to skin		
Rabbit: moderately irritating to eyes		
Guinea pig: not a skin sensitizer		
Nonmutagenic		
NOEL/NOAEL:		
Reproduction.		
Rat (3-generation feed)	> 19	$mg\,kg^{-1}\,d^{-1}$
Teratogenicity.		
Rat (gavage)	3	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	> 3	$mg\,kg^{-1}\,d^{-1}$ (developmental)

ADI: 0.03 $mg\,kg^{-1}\,d^{-1}$ [34]

Trimethacarb [*12407-86-2*] [35]

LD_{50} (rat, oral)	125 – 232	mg/kg
LD_{50} (dog, oral)	225	mg/kg
LD_{50} (rabbit, dermal)	> 2000 to > 2500	mg/kg
Rabbit: not a skin irritant		
Rabbit: mild eye irritant		
Guinea pig: not a skin sensitizer		
Nonmutagenic		
NOEL/NOAEL:		
Subchronic.		
Rat (90-d feed)	19 – 21	$mg\,kg^{-1}\,d^{-1}$
Mouse (90-d feed)	119 – 138	$mg\,kg^{-1}\,d^{-1}$
Reproduction.		
Rat (3-generation feed)	< 40	$mg\,kg^{-1}\,d^{-1}$ (parental)
Teratogenicity.		
Rat (gavage)	< 30	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	> 30	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Rabbit (gavage)	< 50	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	> 50	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Chronic.		
Rat (2-year feed)	40	$mg\,kg^{-1}\,d^{-1}$
Dog (one-year feed)	4.6 – 4.9	$mg\,kg^{-1}\,d^{-1}$

ADI: not available

Fentin Acetate [*900-95-8*] [36]

LD_{50} (rat, oral)	140 – 298	mg/kg
LD_{50} (mouse, oral)	81 – 93	mg/kg
LD_{50} (guinea pig, oral)	25	mg/kg
LD_{50} (rabbit, oral)	80	mg/kg
LD_{50} (rat, dermal)	> 2000	mg/kg
LD_{50} (mouse, dermal)	350	mg/kg
LC_{50} (rat, 4-h inhalation)	0.044	mg/L air
Rabbit: nonirritating to skin		
Rabbit: severe irritant to eyes		
Guinea pig: not a skin sensitizer		
Nonmutagenic		
NOEL/NOAEL:		
Reproduction.		
Rat (2-generation feed)	0.4	$mg\,kg^{-1}\,d^{-1}$ (parental and developmental)
Teratogenicity.		
Rat (gavage)	3.2	$mg\,kg^{-1}\,d^{-1}$ (maternal and developmental)
Rabbit (gavage)	0.1	$mg\,kg^{-1}\,d^{-1}$ (maternal)
	0.32	$mg\,kg^{-1}\,d^{-1}$ (developmental)
Chronic.		
Rat (2-year feed)	< 0.3	$mg\,kg^{-1}\,d^{-1}$
Mouse (2-year feed)	1.0	$mg\,kg^{-1}\,d^{-1}$
Dog (one-year feed)	0.2	$mg\,kg^{-1}\,d^{-1}$

ADI: 0.0005 $mg\,kg^{-1}\,d^{-1}$

Niclosamide [*50-65-7*] [37]

LD_{50} (rat, oral)	3710 to ≥ 5000	mg/kg	
LD_{50} (mouse, oral)	1500	mg/kg	
LD_{50} (rabbit, oral)	> 5000	mg/kg	
LD_{50} (cat, oral)	> 1000	mg/kg	
LD_{50} (dog, oral)	> 250	mg/kg	
LD_{50} (rat, dermal)	> 1000	mg/kg	
LC_{50} (rat, 4-h inhalation)	20	µg/L air	[11, p. 874]

Rabbit: severe eye irritant [11, p. 874]
Rabbit: skin irritant, after repeated exposure [11, p. 874]
Nonmutagenic [11, p. 874]
NOEL/NOAEL:
Chronic.

Rat (2-year feed)	100 – 400	$mg\,kg^{-1}\,d^{-1}$	[11, p. 874]
Mouse (2-year feed)	30	$mg\,kg^{-1}\,d^{-1}$	[11, p. 874]
Dog (one-year feed)	100	$mg\,kg^{-1}\,d^{-1}$	[11, p. 874]

ADI: $3\,mg\,kg^{-1}\,d^{-1}$ [11, p. 874]

1. Introduction [1–4]

Molybdenum commonly occurs in nature as the mineral molybdenite, MoS_2, and is found as veins in quartz rock. It was discovered by SCHEELE in 1778, but for the next hundred years, molybdenite was merely a laboratory curiosity. The first major use came during World War I when additions of molybdenum produced steels with excellent toughness and strength at high temperatures for use as tank armor and in aircraft engines.

Historical Aspects. The main source of molybdenite throughout the 19th century was the Knaben mine in Norway in which the molybdenite was concentrated by hand. The World War I demand for molybdenum, however, spurred development of the Climax Mine (Colorado), which was put on stream in 1918 by the Climax Molybdenum Company. By that time the froth flotation process had replaced hand sorting for concentrating ores.

Although the Climax Mine was closed after the war because of the suddenly decreased demand, it was reopened in 1924 as new peacetime uses of molybdenum, largely in the automotive industry, were developed. Demand for molybdenum steadily grew as new chemical and metallurgical applications continued to be developed, largely stimulated by the research efforts of the Climax Molybdenum Company.

In 1933 a process for the selective flotation of molybdenite from copper porphyry ores was developed by the Anaconda Company at its Greene Cananea subsidiary in Mexico. The Kennecott Copper Company soon followed at its Utah mines. The technology was later extended to Chile at Kennecott's El Teniente Mine and Anaconda's Chuquicamata mine. Thus began the age of molybdenum production as a byproduct of copper.

During World War II, the United States supplied about 90 % of the world molybdenum demand, most coming from Climax with the balance from Kennecott's Utah mines and Molycorp's Questa mine. The largest of the other Western-world producing countries were Chile, Mexico, and Norway.

Climax Molybdenum Company continued to be the largest Western-world producer into the 1980s, doubling its capacity when it opened the massive Henderson mine (near Empire, Colorado) in 1976. Production from Mexico and Norway remained small, but less expensive byproduct molybdenum production from Chile and the United States continued to grow, and the Endako and other mines in Canada began molybdenum production. In 1977, total world production exceeded 200×10^6 pounds (ca. 90 000 t) for the first time.

During the late 1970s the high price of molybdenum stimulated the opening of several new primary mines and the expansion of many byproduct molybdenum facilities. When the price declined in the early 1980s, byproduct molybdenum became the dominant economic force in the marketplace. Climax Molybdenum Company closed the underground mine at Climax, but was still a major producer with the Henderson mine and the open pit at Climax. Cyprus Minerals, with four operating mines, became a major producer. Other important Western-world producers at the end of the 1980s were Codelco's Chuquicamata mine in Chile, Placer's Endako mine in Canada, the La Caridad mine in Mexico, and the Cuajone and Toquepala mines in Peru. Annual world production and consumption averaged $(180-200) \times 10^6$ pounds (80 000 – 90 000 t) of molybdenum during the late 1980s.

2. Properties

Physical Properties. Molybdenum [*7439-98-7*], Mo, A_r 95.94 ± 0.01, atomic number 42, electronic configuration $[Kr]\,4d^5\,5s^1$, is the second member of group 6 of the periodic table. As a transition element it may have a valency of 2, 3, 4, 5, or 6. In the massive state molybdenum is a lustrous silver-white solid with typically metallic properties. When produced as a powder it is dull grey. It has a body-centred cubic lattice with $a_0 = 0.31472$ nm. The physical properties of molybdenum depend to a large degree on the method used to produce it and on its subsequent treatment. For example, its relative density calculated from a_0 is 10.22 whereas an earlier measurement gave 9.01 and later work showed that the lower value increases with the amount of mechanical working to which the metal is subjected. The accepted values of the main physical properties of the metal are given below. A more

extensive compilation is available giving, in particular, data of importance to metallurgists [5].

mp	2617 °C
bp (101.3 kPa)	4612 °C
Latent heat of fusion at *mp*	35.6 kJ/mol
Mean specific heat (0 – 100 °C)	251 J kg^{-1} K^{-1}
Density (20 °C)	10.22 g/cm^3
Thermal conductivity (0 – 100 °C)	137 W m^{-1} K^{-1}
Electrical resistivity (20 °C)	5.7 μΩ · cm
Temperature coefficient (0 – 100 °C)	4.35×10^{-3} K^{-1}
Elastic constants of polycrystalline metal (20 °C)	
Young's modulus	324.8 GPa
Rigidity modulus	125.6 GPa
Bulk modulus	261.2 GPa
Poisson's ratio	0.293
Linear coefficient of thermal expansion (0 – 100 °C)	5.1×10^{-6} K^{-1}
Standard electrode potential $E^0_{Mo^{3+},Mo}$	− 0.200 V

Chemical Properties. Molybdenum retains its luster almost indefinitely in air, particularly when it has been drawn to fine wire. It can be passivated by oxidation, especially by electrolytic oxidation, becoming chemically unreactive. On prolonged heating in air below 600 °C, the metal becomes covered with its trioxide; at 600 °C the oxide sublimes and rapid oxidation occurs. Molybdenum burns in oxygen at 500 – 600 °C. It is slowly oxidized by steam, is attacked by fluorine when cold and by chlorine and bromine when hot. Dilute acids and concentrated hydrochloric acid have very little effect on the metal. Moderately concentrated nitric acid dissolves it but concentrated nitric acid soon passivates the surface and reaction ceases. Molybdenum is dissolved by a mixture of concentrated nitric and concentrated hydrofluoric acids. It is practically unaffected by alkaline solutions and very nearly so by fused alkali-metal hydroxides. However fused oxidizing salts such as sodium peroxide, sodium or potassium nitrate or perchlorate dissolve the metal rapidly. It reacts on heating with carbon, boron, nitrogen, and silicon and forms many alloys. It is used in a variety of catalysts, especially combined with cobalt in the desulfurization of petroleum. Molybdenum is a biologically active metal which is involved in the functioning of enzymes causing reduction of nitrogen to ammonia, and of nitrates.

3. Occurrence

3.1. Minerals

Molybdenum occurs in the earth's crust in an abundance of about 10^{-4} %, mainly as molybdenite [*1309-56-4*], MoS_2. Small quantities are also associated with other metals having similar chemical properties. Thus wulfenite [*14913-82-7*], ($PbMoO_4$) is found in oxidized parts of sulfidic lead deposits in many regions of the world; powellite [*14020-51-0*], [$Ca(Mo,W)O_4$] is a calcium molybdate usually formed from the modification of molybdenite in deposits containing tungsten as scheelite ($CaWO_4$) and tungsten substitutes for molybdenum up to about 10 %. Ferrimolybdite [*15079-04-6*] ($Fe_2Mo_3O_{12} \cdot 8\,H_2O$) is the product of oxidation of molybdenite in the presence of iron(III) compounds. Molybdenite is the primary source of molybdenum. Should demand for molybdenum rise so that additional sources become necessary, wulfenite, powellite, and ferrimolybdite may become commercially significant. Other molybdenum minerals include achrematite, belonesite, chillagite, eosite, ilsemannite, jordisite, koechlinite, lindgrenite, and paterite. These are of no commercial importance however.

3.2. Deposits

There are five genetic types of molybdenum deposits:

1) porphyry deposits in which metallic sulfides are disseminated throughout large volumes of altered and fractured rock,
2) contact-metamorphic zones and bodies in which silicated limestone is adjacent to intrusive granites,
3) quartz veins,
4) pegmatites, and
5) deposits bedded in sedimentary rocks.

Types (1) – (3) are of hydrothermal origin and provide almost all of the molybdenum ore currently mined. The last two are of no economic importance at present. Average molybdenite concentrations in primary porphyry deposits range from 0.05 to 0.25 %; in

secondary copper – molybdenum porphyry deposits molybdenite concentrations are much lower (0.01 – 0.05 %) so that the mineral can only be recovered as a byproduct.

In hydrothermal deposits, the cracks and interstices of the intrusive rock forming the matrix were originally penetrated by aqueous metal-containing solutions. Such solutions are often formed close to magma and so are at a high temperature and pressure and contain sulfide species. As the solution cools, minerals are deposited within the intrusive matrix and also commonly in the surrounding country rock. Thus the famous deposit at Climax, Colorado (USA) was formed by an intrusion of a quartz – monzonite magma into a granitic country rock. The hydrothermal solution deposited quartz and molybdenite in even the smallest fractures so that the host rock appears to consist of angular fragments separated by narrow bands of the minerals. In many porphyry deposits small amounts of molybdenite are disseminated with copper sulfide minerals throughout large volumes of granitic rock. The chief mineral values are chalcopyrite ($CuFeS_2$) and chalcocite (Cu_2S), associated with pyrite (FeS_2), and small amounts of other sulfides, including molybdenite. Where secondary enrichment of the copper ore has occurred, chalcocite has replaced pyrite and chalcopyrite. In limestone – silicate sedimentary rocks containing intrusions of granitic rocks, small amounts of molybdenite are occasionally widely distributed along the interfaces between the rocks and are often associated with scheelite ($CaWO_4$), bismuthinite (Bi_2S_3), or copper sulfides. These deposits may contain up to 0.6 % molybdenite.

Pegmatites are the result of igneous activity and subsequent solidification of the magma. The slow cooling of the mass results in the formation of coarse crystals, almost exclusively of quartz and feldspar. Molybdenite occurs in small amounts as an accessory mineral, usually as large crystals; pegmatites are not an important source of molybdenum. Nevertheless, a pegmatite deposit containing molybdenite together with bismuth was mined until recently at Val d'Or and Preissac (Quebec, Canada). Sedimentary rocks in which molybdenum minerals may occur include coals, shales, phosphorites, and sandstones. They are not used as sources of molybdenum and the technology to recover it from them has not been developed.

Molybdenum is obtained commercially almost exclusively from molybdenite, which is either mined and concentrated as the primary product of the mine or open pit, or recovered as a concentrate during the processing of ore from a copper mine. In the latter case the molybdenite can be either a by- or a coproduct, depending on its economic importance to the output of the mine. Molybdenum is also recovered from solutions obtained by leaching scheelite ores in the production of tungsten. Molybdenum supply in the Western world can be broken down into four production segments (see also Chap. 10) [6]:

1) primary mine production (ca. 40 %),
2) by- or coproduction output from copper and scheelite mines (ca. 55 %),
3) imports from the People's Republic of China (3 %), and
4) molybdenum recovered from the processing of spent petroleum catalyst (2 %).

Reserves of molybdenite in the market economy countries have been estimated by evaluating identified ore bodies [7], i.e., those which have been explored as well as those which have been exploited. The results indicate the following amounts of recoverable molybdenum (10^3 t): United States, 4100; Chile, 1770; Canada, 928; Mexico, 306; Peru, 288; other countries, 356. Ore bodies producing primarily molybdenum contain 55 % of the reserves identified; only 29 % of these ore bodies were being exploited at the time of the survey (January 1985). Properties producing molybdenum as a byproduct contained the remaining 45 % of reserves and 67 % of them were producing molybdenite. The total recoverable molybdenum from primary and byproduct reserves has been estimated as follows (10^3 t molybdenum in concentrate) [8]:

Primary producing properties	1265
Primary nonproducing properties	3036
Byproduct producing properties	2316
Byproduct nonproducing properties	1142

Molybdenum occurs widely in all continents but usually in small quantities. The large-scale mining, milling, and processing facilities now required for economic production of molybdenum compounds are only justified where large

reserves of ore exist. Where these are exploited they are the primary molybdenum producing mines. In Canada, Endako (Placer Dome) is the only primary molybdenum mine and is in British Columbia. The Cumobabi mine (Empresso Frisco SA de CV) is in Mexico; the Jinduicheng mine is the largest molybdenum producer in China and all of the others, except perhaps for some in the Soviet Union, are in the United States. In Alaska, Quartz Hill is under long-term development. The famous, very large Climax and Henderson mines (both Amax) are in Colorado; Thompson Creek (Cyprus Minerals) is in Idaho; Tonopah (Cyprus Minerals) is in Nevada; and Questa (Molycorp) is in New Mexico. A detailed list of major molybdenum-producing companies is given in [8] (see also Chap. 10).

Molybdenum is extracted as a byproduct or coproduct of copper production in Canada, Chile, Iran, Mexico, Papua New Guinea, Peru, Philippines and, in the United States (Arizona, Nevada, New Mexico, and Utah). It is extracted from the scheelite mine at Sang-dong, Gangwon-do, Korea (Korea Tungsten Mining) as a byproduct of tungsten recovery.

4. Production

4.1. Concentration [9]

Molybdenum ore is mined by underground and open-pit methods. A typical primary molybdenum ore body contains 0.05 – 0.25 % Mo, and secondary ore bodies (copper porphyry ores) average 0.3 – 1.6 % Cu and 0.01 – 0.05 % Mo. Flotation (→ Flotation) remains the preferred and almost exclusive method of upgrading the molybdenite mineral to an industrial-grade molybdenite concentrate containing 90 – 95 % MoS_2 [*1317-33-5*], the balance being gangue.

The flotation process [10], [11] starts by pulverizing the ore to liberate the molybdenite (either alone or in association with copper sulfide minerals) from the host rock (mainly quartz monzonite), and then agitating the pulverized ore with water, a collector oil, and other special chemicals to cause preferential wetting of the host rock particles. The unwetted copper and molybdenum mineral particles are carried to the surface by air bubbles as the wetted host rock particles settle or remain suspended. A frothing agent is used to stabilize the bubbles, which contain the sulfide minerals, for easy skimming from the surface.

Molybdenite flotation is so spontaneous that it is termed a natural floater. Other minerals, such as clay and covellite (CuS), that are commonly associated with molybdenite-containing ores are, however, also natural floaters. For this reason the flotation process for molybdenum production from primary ore bodies differs from that of secondary ore bodies. Factors such as the grinding method, particle size, alkalinity, slurry density, and reagent usage dictate the recoveries and process economics.

Figure 1. Primary molybdenite recovery process [9]

Recovery from Primary Ore Bodies. Figure 1 illustrates a basic recovery flowsheet from a primary molybdenum ore body. Although the methods of comminution vary, the objectives are to break down the ore to liberate the molybdenite. For example, Climax uses primary, secondary, and tertiary crushing with screening and rougher ball mills in closed circuit with

spiral and hydrocyclone classification to produce a flotation feed [12]. Henderson [13] and Thompson Creek [14] use primary crushing and semi-autogenous grinding in closed circuit with hydrocyclone classification. Detailed descriptions of comminution methods are given elsewhere, → Size Reduction.

An initial primary grind [ca. 48 % – 200 mesh (74 μm)] is usually acceptable to produce a 2.5 – 5.0 % Mo concentrate in the first "rougher" flotation stage. This concentrate is then upgraded by further grinding and "cleaner" floating. This concept of upgrading progressively smaller volumes of concentrate has proved to be the most cost effective means of handling large tonnages of low-grade molybdenum ores.

Sufficient regrind and cleaner steps follow to obtain the degree of liberation required for a final concentrate grade. For example, six cleaner flotation steps are used at Thompson Creek [14], five at Climax [12], and four at Henderson [13]. The nonfloat from the last stage of cleaner flotation is circulated countercurrently through the previous cleaner stages. Overall recovery is generally about 85 %.

At each flotation step molybdenite particles are floated and collected, and contaminants are depressed and rejected by adding reagents. Different reagent programs are used depending on the properties of the mined ore [15]. Simple hydrocarbon collectors can be used such as kerosene, stove oil, or light oil. Pine oils and Syntex VB (sulfated monoglyceride of coconut oil), which also have emulsifying and collecting properties, are used as frothers; lime or soda ash is used to control alkalinity, usually at pH 8.5. Contaminants are rejected by controlling the pH at an optimum level and by adding depressing reagents such as Noke's reagent (a product formed by reaction between stoichiometric quantities of sodium hydroxide and phosphorus pentasulfide) and sodium cyanide. Sodium silicate is used to disperse slimes.

Recovery from Secondary Ores. The generally accepted practice for secondary molybdenum recovery (Fig. 2) is to float a copper – molybdenum sulfide concentrate and then extract the molybdenum from the combined concentrate by methods governed by the type of copper mineralization present.

Figure 2. Byproduct copper – molybdenite recovery process [9]

In practice, fine grinding [50 – 70 % – 200 mesh (74 μm)] is usually performed to maximize copper recovery [16]. Then bulk flotation of the molybdenum – copper sulfide concentrate generally employs strong alkyl xanthates (e.g., potassium amyl xanthate or sodium isopropyl xanthate) and nonselective frothers (e.g., methylisobutylcarbinol) to float as much of the total copper – molybdenum product as possible.

The bulk copper – molybdenum flotation stream is thickened by settling the solids and decanting the clear process water to obtain a copper – molybdenum slurry with a higher solids content. The slurry is conditioned by

adding reagents during the thickening step as a method of premixing the reagents that will be used in the rougher flotation step.

On a worldwide basis, molybdenum losses in the copper – molybdenum bulk flotation process amount to about 48 % of the total molybdenum feed, but this level is gradually being reduced. Most of the molybdenum losses are incurred because the circuits are designed and operated for optimum copper recovery.

Selective collectors [17] are then used for separating molybdenum from the bulk copper – molybdenum concentrate beginning in the rougher flotation stages. For example, chalcopyrite ($CuFeS_2$), the most common type of copper mineralization, is particularly amenable to sodium hydrosulfide treatment. It is depressed with a 40 % solution of sodium sulfide or hydrosulfide. The hydrosulfide ion in the solution preferentially desorbs the bulk collector from the copper sulfide mineral, leaving it in the water-wetting, nonfloating condition.

Hypochlorides, peroxides, permanganates, and dichromates can also oxidize the adsorbed collectors giving an initial depressing effect to copper sulfides; cyanides will further depress copper to yield a high-grade molybdenite concentrate. When using these oxidants and depressants, chalcocite (Cu_2S) ores require more circuit design, i.e., additional flotation stages and more reagent addition points.

Covellite (CuS) ores float naturally and have been removed from flotation (depressed) with lignin sulfonate but now the simpler process of adding excess collector is used. Clays have been depressed with aluminum sulfate. Noke's reagent is a strong but short-lived depressant of copper sulfides. Lime is used for pH control at 9.5 – 11.5 to diminish pyrite flotation.

Sufficient grind and cleaner steps follow to obtain the desired degree of separation of the copper ore and molybdenite. Common reagents used for cleaner flotation are diesel oil and other light hydrocarbons. The nonfloat copper ore is filtered and dried before being converted to copper metal by smelting. The floated MoS_2 is filtered to remove bulk water. The wet, oily MoS_2 is not treated any further before roasting to MoO_3.

A careful balance of all reagent combinations must be determined in actual plant practice. The scarcity of collector oils has initiated intensive studies of collector substitutes, and environmental considerations are causing concentrators to move away from cyanides, arsenates, chromates, and other hazardous reagents.

Figure 3. Multiple-hearth roasting furnace of the Nichols – Herreshoff type [20]
a) Rotating hollow shaft for passage of air to hearth; b) Rabble arms connected to shaft; c) Multilevel hearths; d) Beveled gear; e) Motor; f) Drive gear

4.2. Processing of Concentrate

Direct Use. Some commercial-grade molybdenite concentrate is subjected to additional grinding and flotation to produce lubricant-grade molybdenum disulfide (99 % MoS_2). Residual flotation oils and water are then volatilized by passing the upgraded concentrate through an inert-gas-swept kiln. This high-

purity product is added to grease and oils as a solid lubricant.

Production of Molybdenum Trioxide. The principal commercial molybdenum product is *technical-grade molybdenum trioxide* (MoO_3) [*1313-27-5*]. In addition to being the major compound for adding molybdenum to steel, it is also the starting compound for all other molybdenum products including ammonium dimolybdate, pure molybdenum trioxide, sodium molybdate, molybdenum metal (Sections 4.3 and 4.4), and ferromolybdenum (Chap. 6).

Molybdenite is converted to technical-grade MoO_3 by roasting it in air in a multiple-hearth furnace of the Nichols–Herreshoff or Lurgi design [18], [19], (Fig. 3). The roasted MoO_3 product typically contains $< 0.1\,\%$ sulfur. The multiple-hearth furnace is used because the hearths can be segmented to accomplish specific and different conversion operations within a single unit. Figure 4 shows the hearth-by-hearth composition of the molybdenum during roasting [18].

Figure 4. Composition of molybdenum sulfide and oxide in multiple-hearth roasting [18]

The upper hearths of the furnace are mainly used to burn off flotation oils and evaporate water. This part of the process is usually augmented by burning fossil fuels to ensure consistent temperature control and uniform roasting throughout the remainder of the unit. Upper hearth temperatures range between 600 and 700 °C.

The bulk of the sulfur is removed by oxidation in the intermediate hearths:

$$2\,MoS_2 + 7\,O_2 \rightarrow 2\,MoO_3 + 4\,SO_2$$

$$MoS_2 + 6\,MoO_3 \rightarrow 7\,MoO_2 + 2\,SO_2$$

$$2\,MoO_2 + O_2 \rightarrow 2\,MoO_3$$

Since the sulfur oxidation reactions are highly exothermic, additional heating is not needed in this section. The hearth temperatures are controlled between 600 and 650 °C by the addition of excess air and/or with water spray cooling.

As sulfur burning nears completion, the composition of the roaster hearth is mostly MoO_2 with $< 20\,\%$ MoO_3 and MoS_2. The reaction of MoO_3 with MoS_2 to form MoO_2 is driven by the strong oxidizing power of MoO_3, so that the production of MoO_3 is limited until most of the MoS_2 is gone.

Once the availability of MoS_2 is less than the availability of MoO_3, MoO_2 is rapidly converted to MoO_3. Although this reaction is exothermic, it is not sufficient to maintain the temperatures above 525 °C which are required to complete sulfur removal and conversion to MoO_3. Hence supplementary heating is required in these lower hearths. The oxide product is discharged from the roaster, cooled, and milled to form technical-grade MoO_3. Technical-grade MoO_3 typically contains 85–90 % MoO_3, the balance being silica with some Fe_2O_3 and Al_2O_3.

Sulfur dioxide and sulfur trioxide leave the roaster in the flue-gas stream. This gas stream is handled by methods which comply with emission regulations. The most common are contacting the off-gas with lime to produce disposable $CaSO_4 \cdot 2\,H_2O$ and the production of sulfuric acid. Sulfuric acid is produced by catalytically oxidizing the sulfur dioxide to sulfur trioxide which is absorbed by a H_2SO_4 solution.

In addition to sulfur removal, certain metal contaminants tend to vaporize during the roasting process. Any rhenium oxide [*1314-68-7*], Re_2O_7, in the concentrate can be scrubbed from the off-gas stream and recovered by solvent extraction or ion-exchange processes (→ Rhenium and Rhenium Compounds). Selenium oxide [*7446-08-4*], SeO_2, is also preferentially vaporized and can be collected to avoid creating an environmental hazard.

In many cases chemical leaching of the concentrate is required prior to roasting to preferentially remove nonferrous impurities detrimental to steel production. Three leaching processes are practiced:

1) sodium cyanide leachate is used for copper and gold removal;
2) iron(III) chloride for copper, lead, and calcium removal; and
3) hydrochloric acid for lead and bismuth removal.

Pure molybdenum trioxide can be produced from technical-grade MoO_3 via calcination of ammonium dimolybdate (ADM) or by sublimation.

Ammonium dimolybdate [*27546-07-2*] is obtained by first leaching the technical-grade oxide with water at ca. 75 °C to remove soluble alkali impurities, primarily potassium [20], [21]. The oxide is then filtered and dissolved in a 10 – 20 % ammonium hydroxide solution at 40 – 80 °C to form ammonium molybdate:

$$MoO_3 + 2\,NH_3 + H_2O \rightarrow (NH_4)_2MoO_4$$

The ammonium molybdate solution is separated from the insoluble gangue minerals (primarily silica and some iron) by filtration and then further purified by precipitation of the heavy metals (e.g., copper) with sulfide. The filtered solution is then fed to an evaporative crystallizer operating at atmospheric pressure to produce ADM crystals:

$$2\,(NH_4)_2MoO_4 \rightarrow (NH_4)_2Mo_2O_7 + 2\,NH_3 + H_2O$$

Varying degrees of rejection for sodium, calcium, magnesium, and aluminum occur during crystallization and these impurities build up in the mother liquor. They are eliminated by periodic purging of the crystallizer. The ADM crystals are recovered by centrifugation and then dried. Calcining the ammonium dimolybdate in an indirectly fired rotary kiln at temperatures in excess of 420 °C produces pure MoO_3.

Pure MoO_3 is also produced by *sublimation* of technical-grade MoO_3 [22]. The oxide is heated to 1100 – 1200 °C as a thin layer on a doughnut-shaped furnace hearth that rotates under electrical resistance heating elements. Air is drawn over the heated surface and sweeps away the vaporized MoO_3, leaving the nonvolatile gangue and other metallic impurity elements behind. The charge on the hearth makes one pass under the heating elements. The residue, still rich in molybdenum, is discharged for use as a steel additive. The sublimation yield is about 60 – 70 %. The sublimed vapor is then cooled, condensed, and collected in baghouses prior to densifying, screening, and packaging.

The molybdenum oxides produced by the ADM and sublimation processes are both of high purity (99.9 % MoO_3). Compared to calcined ADM, sublimed pure oxide has a significantly lower alkali content, but higher silica, iron, lead, and tin levels. Sublimed pure oxide also tends to be finer in size and acicular (needlelike) in shape.

Sodium molybdate [*7631-95-0*] (and other similar molybdates) may also be produced from technical-grade MoO_3 [23], although pure MoO_3 is a common, but more expensive, starting material. Technical-grade MoO_3 is leached as in the ADM process and then dissolved in sodium hydroxide at 50 – 70 °C to produce an almost saturated solution of sodium molybdate. A minimum excess of caustic (NaOH) is maintained to inhibit silica dissolution; a small quantity of sulfide ion is added to precipitate heavy metals. If pure oxide is used, the initial leaching step is eliminated.

After filtration, the solution is fed to an evaporative crystallizer to produce sodium molybdate dihydrate ($Na_2MoO_4 \cdot 2\,H_2O$). If crystallization is performed below 10 °C, the decahydrate is formed ($Na_2MoO_4 \cdot 10\,H_2O$). The crystals are recovered by centrifugation and dried at 70 °C. Anhydrous sodium molybdate (Na_2MoO_4) is produced by drying at > 100 °C.

4.3. Recovery from Spent Petroleum Catalysts

Molybdenum-containing catalysts are widely used in the petroleum refining industry for mild hydrogenation and removal of heteroatoms such as sulfur (hydrodesulfurization), nitrogen, and oxygen, as well as metals like nickel and vanadium. A typical catalyst uses molybdenum in combination with cobalt or nickel on a porous alumina (Al_2O_3) support. The composition range of such a catalyst when spent is 2 – 10 % Mo, 0 – 12 % V, 0.5 – 4 % Co, 0.5 – 10 % Ni, 10 % S, 10 % C, with the balance being Al_2O_3.

Numerous approaches have been explored to recover the metal values from spent catalysts. The fundamental strategy involves:

1) Initial heat treatment in air to remove the residual sulfur, carbon, and hydrocarbons,

and to oxidize the metals to soluble molybdate and vanadate.
2) A leaching step resulting in preferential solubilization of molybdate and vanadate, leaving the Ni – Co – alumina as a solid.
3) Separation of the Mo and V.
4) Treatment of the Ni – Co – alumina residue to recover Ni and Co.

Production of Molybdate and Vanadate. One basic process is to roast the ground (– 100 mesh, < 149 μm), spent catalyst in air at 600 °C and then mix the roasted material thoroughly with soda ash (Na_2CO_3) [24]. The Na_2CO_3 – spent catalyst mix is roasted again in air at 600 – 800 °C to convert the molybdenum and vanadium oxides to soluble sodium molybdate and sodium vanadate, respectively:

$$MoO_3 + Na_2CO_3 \rightarrow Na_2MoO_4 + CO_2$$

$$V_2O_5 + Na_2CO_3 \rightarrow 2\,NaVO_3 + CO_2$$

The roasted mix is leached with water at up to 100 °C to dissolve the soluble molybdenum and vanadium compounds. The molybdenum- and vanadium-containing solution is recovered by filtration for subsequent separation; the insoluble Ni – Co – alumina filter cake is treated separately to recover the respective metal values. A similar process uses sodium chloride instead of soda ash and results in the same sodium molybdate – sodium vanadate solution [25].

An alternative process uses wet-air oxidation to combine the first two oxidation steps [26]. The as-received and ground (– 100 mesh, < 149 μm) spent catalyst is slurried with water and soda ash at temperatures up to 300 °C and air pressures up to ca. 17 MPa (2500 psi). The molybdenum and vanadium sulfides are directly converted to soluble sodium molybdate and vanadate, respectively:

$$2\,MoS_2 + 6\,Na_2CO_3 + 9\,O_2 \rightarrow 2\,Na_2MoO_4 + 4\,Na_2SO_4 + 6\,CO_2$$

$$4\,VS + 6\,Na_2CO_3 + 11\,O_2 \rightarrow 4\,NaVO_3 + 4\,Na_2SO_4 + 6\,CO_2$$

In addition all the carbon and hydrocarbons are oxidized (burned off). The nickel and cobalt sulfides are also oxidized and the sulfur is converted to sodium sulfate. The Ni – Co – alumina remains insoluble as in the previous processes.

Recovery of Molybdenum and Vanadium. A number of technologies are available for recovering the metal values from the molybdenum- and vanadium-containing solution [26]. For example, addition of ammonium chloride or ammonium sulfate precipitates the vanadium as ammonium vanadate, $(NH)_4VO_3$, which is removed by filtration [24]. The molybdenum can then be precipitated as calcium molybdate by adding lime.

In another method, treating the solution with hydrogen sulfide under very acidic conditions (1 – 2 mol/L H_2SO_4) preferentially precipitates molybdenum trisulfide. The vanadium remaining in solution can be precipitated as the hydrated oxide, $V(OH)_4 \cdot 1.5\,H_2O$, by neutralization of the solution with sodium hydroxide, or as red cake ($Na_2H_2V_6O_{17}$) by first oxidizing the vanadium in solution with $NaClO_3$ and adjusting the pH to about 6 with NaOH or Na_2CO_3. In a final solvent extraction method the vanadium is preferentially extracted from the solution with a quaternary ammonium compound such as Aliquat 336 (tricapryl monomethyl ammonium chloride). The molybdenum can then be extracted with a secondary amine such as Adogen 283, a ditridecylamine.

Recovery of Nickel and Cobalt. A number of technologies are also available to recover the nickel and cobalt from the alumina. They can be leached from the alumina with 5 % HCl or H_2SO_4 solution at 75 °C [27]. They can also be recovered by caustic digestion of a slurry of the Ni – Co – alumina residue in a 25 % caustic (NaOH) solution at 250 °C for 2 h [26]. The dissolved nickel and cobalt are recovered and separated by other methods standard in the nickel industry.

4.4. Recovery during Production of Tungsten Ores

The occurrence of tungsten ores, such as scheelite ($CaWO_4$), is commonly associated with trace amounts of powellite ($CaMoO_4$). Most of the powellite stays with the scheelite during its processing to a sodium tungstate solution by soda ash digestion in an autoclave. The powellite

forms sodium molybdate and is solubilized. This is not a significant source of molybdenum and the recovered molybdenum is usually discarded because it is contaminated with tungsten. However the molybdate is routinely removed from the tungstate solution to purify the tungsten. For a full description of tungsten production, see → Tungsten and Tungsten Compounds.

The most common method of removing molybdenum from a sodium tungstate solution is to treat the solution with sodium sulfhydrate, $NaSH \cdot 2\,H_2O$ [28]. This compound reacts with the sodium molybdate and some of the sodium tungstate to precipitate the trisulfides, MoS_3 and WS_3, respectively. The precipitate generally contains two to three parts of molybdenum to one part of tungsten; it can be calcined to give the relevant oxides and then leached with strong hydrochloric acid to dissolve the molybdenum, leaving the tungsten.

4.5. Production of Molybdenum Metal Powder [29]

Molybdenum metal powder is produced industrially by reducing high-purity molybdenum compounds with hydrogen. The following compounds are used:

1) Molybdenum trioxide, MoO_3 (grey – green powder).
2) Ammonium hexamolybdate, $(NH_4)_2Mo_6O_{19}$ (yellow powder).
3) Ammonium dimolybdate, $(NH_4)_2Mo_2O_7$ (white powder).

To allow further processing by powder metallurgy, reduction conditions should result in a powder that can be pressed and sintered. Reduction is usually performed in two stages:

1) Reduction to MoO_2 (molybdenum red).
2) Reduction of MoO_2 to molybdenum metal powder.

This gives satisfactory yields of a completely reduced powder with the desired particle size distribution and a sufficiently high specific surface area in a reasonable length of time. Since reduction to MoO_2 is exothermic, this step is performed at 600 °C to prevent caking due to the melting of MoO_3 (*mp* 800 °C). The MoO_2 is reduced to molybdenum powder at ca. 1050 °C. The powder has a particle size of 2 – 10 µm, a specific surface area of 0.1 – 1 m^2/g, and an oxygen content of 100 – 500 mg/kg (partly adsorbed and partly as oxide).

Reduction is usually performed in an electrically heated continuous furnace (e.g., a pusher furnace, a walking beam furnace, or a rotary kiln) with a counterflowing stream of hydrogen. Reduction in fluidized-bed reactors is also known. Introduction of impurities should be avoided at all stages. Molybdenum powder 5N5 with an impurity content of ≤ 5 mg/kg can be produced; this figure does not, however, take into consideration gases and refractory metals. Special purification procedures such as multiple recrystallization, ion exchange, solvent extraction and adsorption are used to remove undesirable impurities such as alkali metals, ferrous metals, and radioactive elements from molybdenum to be used in the semiconductor industry. Special mixer linings, furnace linings, and sintering boats prevent contamination with iron and ceramic particles.

Good flow properties and a constant apparent density are critical for satisfactory processing of molybdenum powder in automatic presses. Molybdenum powder is typically mixed with an organic binder, e.g., poly(vinyl alcohol), and a volatile agent, e.g., water. The slurry is sprayed into a heated free-fall chamber where spherical agglomerates are formed due to surface tension. Heating causes vaporization of the volatile agent, giving a hard, densely packed agglomerate (spray-drying process).

4.6. Production of Compact Molybdenum Metal [30], [31]

More than 95 % of the total world production of molybdenum and molybdenum alloys high in molybdenum is produced by powder metallurgy, the remainder is obtained by vacuum arc remelting and electron beam melting.

Molybdenum produced initially by melting has to be worked by extrusion due to its coarse-grained, columnar microstructure; metal produced by powder metallurgy can, however, be worked by almost all standard hot metalworking techniques.

Production by Powder Metallurgy. More than 99 % of industrially produced molybdenum is prepared by the method shown on the left-hand side of Figure 5. In the case of large workpieces and round bars, the molybdenum powder is filled into rubber containers that are sealed and then compressed isostatically at 100 – 300 MPa. Due to frictional losses, a somewhat higher pressure (150 – 500 MPa) is used with die presses.

Sintering with resistance heating according to the Coolidge method is still used but indirect heating with tungsten heating elements is now the most common method. This procedure has a lower specific energy consumption, produces a homogeneous structure, and can be used to sinter large and complex components. Large items weighing up to 5 t (such as are used in isothermal forging dies) can only be produced by this method.

Depending on furnace design and the molybdenum alloy, sintering is performed at 1600 – 2200 °C for 3 – 30 h in a hydrogen atmosphere. Minimum sinter densities of 90 %, but preferably 95 %, are required to avoid subsequent processing difficulties. Neck formation between the particles starts at ca. 1200 °C and shrinkage at ca. 1600 °C. Addition of small quantities of platinum, palladium, or nickel allows the sintering temperature to be reduced to 1300 °C. These dopants have a low solubility in molybdenum and accumulate at the grain boundaries where they accelerate diffusion but have an adverse effect on ductility.

Production by Melting. Vacuum arc furnaces are used for large-scale melting of molybdenum. Electron beam devices are, however, used for special applications, particularly for the production of sputtering targets. Presintered molybdenum rods are fed into the electric arc furnace as electrodes and melted. In electron beam devices, sintered or hot isostatically compressed molybdenum rods are used. The resulting molybdenum billets are extruded by the Sèjournet process. In this process the heated billet is rolled over a bed of glass powder, which softens during contact, insulates the tooling from the hot billet, and lowers oxidation.

More recent efforts have been directed at producing a fine-grained as-cast structure by vacuum double-electrode remelting or cold hearth electron beam melting. This should give molten molybdenum which can be processed immediately without intermediate hot extrusion.

4.7. Processing of Molybdenum

Manufacture of Semifinished Products. Molybdenum produced by powder metallurgy (PM molybdenum) can be processed into semifinished articles by almost all classical forming techniques. High temperatures are, however, necessary and special equipment and tools are required. In molybdenum produced by melting the initial forming steps are important for obtaining a fine-grained structure.

The sintered starting material first has to be preheated to 1200 – 1400 °C to prevent any damage occurring during the first deformation steps. In this temperature range the tensile strengths of some molybdenum alloys correspond to those of hot-work tool steels at 700 °C. Preheating can be performed in electrical or gas-fired furnaces in a neutral or reducing atmosphere. Processing is carried out in air even though considerable oxidation occurs at this temperature. Embrittlement does not occur because oxygen and nitrogen are almost completely insoluble in molybdenum.

As forming proceeds, ductility increases and the temperature can gradually be reduced to room temperature. After hot and cold working, the molybdenum is subjected to stress-relief annealing at ca. 800 °C.

Large items are produced by press forging. Round products (diameter 10 µm to ca. 200 mm) are manufactured by extruding (Sèjournet method), forging, swagging, rolling, or drawing. Sheets are available in thicknesses of 10 µm to 50 mm.

Manufacture of Finished Products. Molybdenum can be worked by most of the customary techniques (e.g., deep drawing, flow turning). The working temperature should be higher than the ductile-to-brittle transition temperature but lower than the recrystallization temperature (1100 °C).

Molybdenum can readily be machined by chip removal and by electrical discharge. Tools used for milling, turning, and planing should comply with ISO hardmetal K specifications and have a highly positive cutting geometry. Since the cutting edges of the tools must be extremely

Figure 5. Production of molybdenum by powder metallurgy (PM)

sharp, coated indexable inserts are unsuitable. Commercially available emulsions or, in special cases, highly chlorinated hydrocarbons are used as coolants and lubricants.

When ceramic silicon carbide disks are used for grinding, low speeds must be used (≤ 33 m/s) to avoid buildup of heat. Molybdenum is machined by electrical discharge with zinc-coated brass wires and behaves similarly to hard metals. Graphite or tungsten – copper electrodes are recommended for cavity sinking by electrical discharge machining.

Joining [32]. Molybdenum and molybdenum alloys can be welded and brazed but mechanical joining methods are widely used to avoid embrittlement.

Welding. Tungsten inert-gas welding (in gastight chambers filled with argon) and electron-beam welding are usually employed. The oxygen partial pressure must be extremely low (< 0.5 Pa) because molten molybdenum rapidly takes up oxygen which leads to the precipitation of MoO_3 on cooling and thus to pore formation.

Diffusion welding at a welding temperature slightly below the recrystallization temperature (1100 °C) is particularly suitable for workpieces that are to be subjected to high mechanical loading. Resistance welding is primarily used in the electron tube and lamp industries for joining thin wires, ribbons, and foils.

Brazing is a suitable alternative to welding for operating temperatures below 1400 °C. Since the thermal expansion coefficient of molybdenum is about the same as that of graphite, molybdenum – graphite composites with advantageous properties can be produced, particularly for applications in nuclear fusion research and aerospace. Amongst others AgCu, PdCu, PdAg, Zr, and Ti are used as brazing filler materials.

Oxidation-Resistant Coatings [33]. Molybdenum alloys that can withstand oxidizing conditions at high temperature are still not available. Oxidation resistance decreases

drastically above 500 °C and above 600 °C significant loss of material occurs due to formation of volatile MoO_3. Owing to the increasing demand for high-temperature materials (e.g., in aerospace, turbine construction, and chemical reactors), oxidation resistant coatings are being developed to permit the use of molybdenum materials in these applications.

Coatings based on aluminides, silicides, ceramics (e.g., Al_2O_3, ZrO_2), and metals (chromium, noble metals) have been studied. Coating processes such as dip alloying, electroplating, but primarily pack cementation and slurry techniques, as well as plasma spraying, physical vapor deposition, and chemical vapor deposition have all been used.

Coatings based on silicides (e.g., $MoSi_2$, maximum use temperature 1600 °C) and complex silicides (e.g., SiCrFe, maximum use temperature 1500 °C) provide the best protection against oxidation but are only effective for a limited period.

Surface Hardening (→ Metals, Surface Treatment, Chap. 4.). Nitriding, carburizing, and boriding have been increasingly used to increase the surface hardness and abrasion resistance of molybdenum materials. These thermochemical processes harden the surface to a depth of ca. 0.2 mm. Plasma-assisted processes are also becoming more important.

4.8. Molybdenum-Base Alloys [34–36]

Solution hardening and particle hardening are responsible for the strengthening of molybdenum alloys. Commercially available molybdenum alloys are listed in Table 1. The most commonly used is TZM, an alloy that is particle-hardened with carbides. It has a high heat resistance, a high creep resistance, favorable welding properties, and a recrystallization temperature that is at least 300 °C higher than that of pure molybdenum (1100 °C). The MHC, ZHM, and TZC alloys are even more heat resistant due to their more stable carbides. Heat resistance can be increased even further by solution hardening with tungsten in alloys dispersion-hardened with hafnium carbide; ductility is, however, decreased.

Alloying with rhenium increases the strength and ductility, the latter effect is especially pronounced in alloys containing 40 – 50 % rhenium. These alloys also have excellent welding properties.

Doping with potassium silicate or potassium aluminum silicate and a high degree of deformation yield a material that forms large, oriented grains on recrystallization leading to excellent creep properties up to 1800 °C.

Molybdenum – tungsten alloys are extremely resistant to molten zinc and are therefore used in zinc metallurgy for tanks, pipes, pumps, and stirrers.

5. Uses

Molybdenum is mainly used as an alloying element in steel, cast iron, and superalloys (→ Steel) to increase hardenability, strength, toughness, and corrosion resistance. However, only the use of elemental molybdenum and molybdenum-base alloys is discussed in this chapter.

Initially, molybdenum was primarily used in the lamp industry. It is, however, now an increasingly important material in a wide range of applications (Table 2). In high-temperature applications, molybdenum competes with iron-, nickel- and cobalt-base superalloys, ceramics, and other high-melting metals (tungsten, tantalum, and niobium). Superalloys can be used up to 1200 °C; molybdenum materials, especially the carbide-hardened alloys and molybdenum doped with potassium silicate, show adequate heat resistance (see Fig. 6) and creep properties up to 1800 °C. The lack of resistance to oxidation should, however, always be borne in mind. Molybdenum materials have a higher failure tolerance and ductility than ceramics and are less expensive than tantalum and niobium. Heating elements, thermal radiation shields, and furnace ware made of molybdenum are used, for example, in hot isostatic presses, sintering furnaces for the ceramic industry, and heat treatment furnaces.

Table 1. Properties of commercial molybdenum-base materials (amount of deformation, 90 %)

Type of material	Composition, wt %	Hardening mechanism	Recrystallization temperature, ° C	Typical strength at 1000 ° C [a], MPa	ASTM B 386-85 material number [d]
Mo			1100	250	MM 360, 365 PM 361
TZM	Mo, 0.5 Ti, 0.08 Zr, 0.01 – 0.04 C	particle hardening	1400	600	MM 363 PM 364
MHC	Mo, 0.5 – 2.0 Hf, 0.04 – 0.2 C	particle hardening	1550	800	
ZHM	Mo, 0.4 Zr, 1.2 Hf, 0.1 C	particle hardening	1550	800	
TZC	Mo, 1.0 – 1.5 Ti, 0.2 – 0.35 Zr, 0.06 – 0.2 C	particle hardening	1550	800

Table 2. Uses of molybdenum and molybdenum alloys

Area of application	Examples of uses
Lamp and lighting industries	support wires, sealing ribbons, dimming caps
Electronic and semiconductor industries	semiconductor base plates, heat sinks, contact pins, sputtering targets, control grids, klystron and travelling-wave tube components
High-temperature and vacuum furnace construction	heating elements, thermal radiation shields, furnace ware
Glass and ceramic industries	glass-melting electrodes, installations in glass production tanks, drawing dies, crucibles for producing sapphire single crystals
Casting technology and metalworking	forging dies for isothermal forging, extrusion dies, die-casting molds, hot-galvanizing equipment
Coating	spray wire, spray powder, evaporation boats, sputtering targets, components of chemical vapor deposition equipment
Nuclear technology	furnace parts and charging equipment for sintering UO_2; first wall, divertor, and limiter components for experimental fusion reactors
Medicine	rotating X-ray anodes, collimators

Molybdenum is resistant to corrosion by most glasses and is therefore used as an electrode material in electric glass-melting furnaces. Glass produced in such furnaces is of better quality than that produced in fuel-fired furnaces and the process is more acceptable environmentally.

Crucibles and mandrels used to draw quartz glass or crucibles used for making single sapphire crystals have to withstand temperatures up to ca. 2100 °C. Molybdenum ribbon is used for electrical lead-in (e.g., in halogen lamps). In this application a vacuum-tight seal is formed by squeezing the quartz tubing around the ribbon at high temperature (ca. 2100 °C) and pressure. The high heat resistance of molybdenum and its low coefficient of thermal expansion are important prerequisites for these applications.

Electronic applications have and will continue to be a high-growth market for molybdenum parts. Molybdenum disks are used as base plates and heat sinks for power transistors and silicon rectifiers.

Molybdenum is also an important sputtering target material for electronic applications, mainly for codeposition of $MoSi_x$ films from ultrahigh-purity molybdenum and silicon targets. Integrated circuits employing these films have low parasitic capacitances and also low gate and interconnection propagation delays.

Molybdenum layers produced by thermal spraying possess exceptionally good sliding properties and high abrasion resistance. They are deposited on machine components, especially car engine parts such as piston rings, synchrorings, and selector forks.

More than 80 % of the rotating X-ray anodes currently used in clinical diagnostics are made of molybdenum alloys. Loading can be increased by a thin tungsten – rhenium layer on the molybdenum body. Rhenium in tungsten has the same effect on ductility as rhenium in molybdenum and decreases the susceptibility to cracking initiated by thermal stress. Brazing a thick graphite disk onto the back of a target increases its heat and emission capacity.

6. Production of Ferromolybdenum

6.1. Ferromolybdenum Grades

In the steel and foundry industry molybdenum is added to melts, either as technical oxide or in the form of ferromolybdenum [*11121-95-2*]. Table 3 summarizes the internationally standardized ferromolybdenum alloys; the typical molybdenum content ranges from 55 to 75 %. Compared to pure molybdenum, ferromolybdenum dissolves much more easily in the steel melt and is cheaper to produce. Practical experience has shown that alloys with up to 75 % molybdenum do not cause any dissolution problems. Nevertheless there is still a demand for 65 % molybdenum alloys which are even less critical as regards dissolution characteristics. The Fe – Mo phase diagram is shown in Figure 7. Due to the limited information available, the melting temperatures of the alloy at high molybdenum concentrations can only be estimated. In practice they are likely to be considerably lower than indicated by the phase diagram because of significant concentrations of silicon and other impurities.

Figure 7. Fe – Mo phase diagram showing estimated liquidus (L) compositions at higher molybdenum concentrations [37]
α,δ, and R are intermetallic phases.

6.2. Raw Materials

The principal raw materials used for ferromolybdenum production are molybdenum concentrates (see Section 4.1) and technical-grade molybdenum trioxide (see Section 4.2). One method proposed for the production of

Table 3. International specifications for ferromolybdenum

Specification	Symbol/ designation	Composition, wt %

[c] The range of variation within a graded lot should not exceed 3 wt % absolute.

ferromolybdenum used molybdenum concentrates which were reacted with ferromanganese to form ferromolybdenum and manganese sulfide [38]:

$$MoS_2 + 2\,Mn \rightarrow Mo + 2\,MnS$$

Due to the high Gibbs free energy of manganese(II) sulfide formation, this reaction is claimed to yield ferromolybdenum with a relatively low sulfur concentration, but a further sulfur removal step appears to be necessary. This process is not, however, used on a commercial basis.

Technical-grade molybdenum trioxide is commonly used as the molybdenum raw material. Because of its high value and the fact that MoO_3 starts to sublime at 700 °C, (see Section 7.2), electrostatic precipitators or bag houses must be used to collect the molybdenum dust and sublimates for recirculation. Good housekeeping is also essential to minimize molybdenum handling losses.

Two principal processes are used for molybdenum oxide reduction: *carbothermic reduction* in a submerged arc furnace and *metallothermic* reduction. The most commonly applied method is the silicothermic reduction, a type of metallothermic reduction.

6.3. Submerged Arc Furnace Carbothermic Reduction

The carbothermic reduction of MoO_3 can proceed as follows:

$$2\,MoO_3 + 2\,C \rightarrow 2\,MoO_2 + 2\,CO$$

$$MoO_2 + 2\,C \rightarrow Mo + 2\,CO$$

or with formation of molybdenum carbide:

$$MoO_2 + 2.5\,C \rightarrow 0.5\,Mo_2C + 2\,CO$$

The Gibbs free energies of oxide and carbide formation are shown in Figure 8 as a function of temperature. The reduction of MoO_3 starts at fairly low temperatures. If the process were run at these temperatures (i.e., < 600 °C) then Mo_2C would be formed because it is more stable than molybdenum. However, since the process is run at 1700 – 2000 °C, any intermediately formed molybdenum carbide reacts to form molybdenum metal:

$$2\,Mo_2C + MoO_2 \rightarrow 5\,Mo + 2\,CO$$

Figure 8. Gibbs free energy of oxide and carbide formation [39]
T = transformation point; M_M = melting point of metal; M_O = melting point of oxide

Under practical conditions the resulting metal alloy is low in carbon.

Because of the commercial disadvantages of the process, detailed literature describing the process is limited [40–43]. The process was previously run in single-phase 300 – 500 kW and three-phase 1500 – 2000 kW electric arc furnaces. The use of the single-phase arc furnace seems to have been more successful because of its higher energy density within the furnace. A single-phase system with a cylindrical magnesite or carbon-based rammed furnace body and equipped with a bottom carbon electrode is shown in Figure 9. The top electrode is adjustable and the whole furnace arrangement runs on tracks so that it can easily be replaced with a new unit. The process is run batchwise, producing a semimolten metal block and a slag. The slag contains up to 10 % molybdenum oxide and must be retreated by remelting. Melting of a 1.5 – 2 t metal block takes about 20 – 28 h. To separate metal and slag, the furnace assembly must be stripped and later rebuilt for reuse.

Raw materials are technical-grade molybdenum oxide; iron ore or millscale, steel punchings, nail nips or turnings; lime and fluorspar as fluxing agents; and charcoal as reducing agent. To minimize MoO_3 sublimation, the concentrate and carbon material are briquetted. The reaction is started by melting slag from a previous re-

action and adding the briquetted mixture to the slag to avoid molybdenum sublimation. Once the initial reduction to MoO_2 has taken place, sublimation is avoided. The resulting slag consists of some unreduced MoO_2 and FeO which has a higher Gibbs free energy than MoO_2 (see Fig. 8). To improve metal – slag separation, lime and fluorspar are added. The slag should be fluid and is tapped toward the end of the reduction cycle. The metal block is stripped while it is still red hot and quenched in water to aid subsequent crushing. The metal must be hand-sorted to recycle any parts of the block contaminated with slag. The resulting molybdenum-rich slag has to be remelted in a separate process into a low-molybdenum, high-carbon intermediate alloy which is recycled.

Dust, kg	66	

6.4. Metallothermic Reduction

Metallothermic reduction in which silicon (or aluminum) is used to reduce the MoO_3 is the commonly used production process for ferromolybdenum. For a detailed description of this technique, see → Aluminothermic Processes. Its advantages are that it is a single-step process which results in a saleable metal and a low-molybdenum slag and that it requires only basic process equipment. Due to the large difference in the Gibbs free energy for aluminum oxide and silicon dioxide formation compared to molybdenum oxide formation (Fig. 8), the reduction process approaches 100 % molybdenum reduction.

An aluminothermic or silicothermic reaction must be sufficiently exothermic to melt all the reaction constituents resulting in satisfactory separation of the liquid metal and liquid slag phases before cooling. According to SHEMTCHUSHNY, a minimum specific heat of reaction of − 2700 kJ/kg is required for a reaction to be selfsustained [44]. This assumes that no additional heat is added to the reaction (e.g., by preheating the charge or by adding booster oxides and further reducing metal). Consideration of the specific heats of reaction shows that both aluminum and silicon can be used to reduce MoO_3 in selfsustained reactions:

$$2/3\ MoO_3 + Si \rightarrow 2/3\ Mo + SiO_2 \quad -3241\ kJ/kg$$

$$1/2\ MoO_3 + Al \rightarrow 1/2\ Mo + 1/2\ Al_2O_3 \quad -4689\ kJ/kg$$

If aluminum is reacted with MoO_3, the resulting heat of reaction is very high, leading to excessive evaporation of MoO_3 and the danger of an explosion of the reaction mixture.

Consequently, silicon is the preferred reducing element. Furthermore, less silicon is necessary compared to aluminum (stoichiometric consumption is 0.439 kg silicon per kilogram of molybdenum, compared to 0.562 kg aluminum per kilogram of molybdenum) and silicon in the form of ferrosilicon is considerably cheaper than aluminum.

Practical experience, even when using charges much larger than a 200 kg, shows that silicon alone does not result in a selfsustained reaction. Some of the silicon must therefore be replaced with aluminum or other elements with a similar oxygen affinity. Some of the required iron is often added in the form of millscale or iron ore concentrates which react with silicon or aluminum to generate additional heat. Part of the iron remains as FeO in the slag and acts as a fluxing agent. Further fluxing agents are lime and fluorspar, which are necessary to ensure good separation of metal and slag and low molybdenum concentrations (typically $< 1\ \%$) in the slag. The dust generated in the process can contain up to 5 % of the molybdenum in the charge. Any dust and sublimed MoO_3 must be extracted, recovered, and recycled to achieve an overall molybdenum yield of 97 – 99 %.

To achieve reproducible reactions, a homogeneous mixture of the precisely weighed reaction ingredients is required. All ingredients must be dry, well-calcined, and ideally their particle size should be < 1 mm. A typical firing arrangement is shown in Figure 10. The crucible unit consists of a circular or square, sand- or brick-lined base section and a cylindrical refractory-lined, steel section that contains the reaction slag. The mix feeding arrangement allows part of the reaction mixture to be placed into the well-dried crucible unit. The reaction is started by adding a small amount of a mixture of barium peroxide and aluminum to a special starter mix which tends to be more exothermic than the main mix. Once the main mix has started to react, the bulk of the reaction mix is continuously fed into the crucible arrangement. Total reaction times of 30 – 60 min for metal block weights of 1 – 4 t can be expected. After completion of the reaction, metal and slag are allowed to segregate for another 30 – 60 min before the bulk of the slag is tapped off. The red-hot metal block is then stripped off the furnace base and quenched in water to aid crushing. Jaw crushers are commonly used for crushing the metal. Considerable care has to be taken when sampling the metal for molybdenum content because the molybdenum tends to segregate within the block. Any highly segregated metal and metal contaminated with slag inclusions is recycled for remelting. Good housekeeping is necessary to recycle all splashings, floor sweepings etc. and achieve a good total molybdenum yield.

In a process modification used by Duval Corporation, Duval Sierrita [46], the entire reaction mix is charged into the reaction crucible before ignition. The advantage is that controlled addition of the reaction mix is not required. The disadvantages are that the reaction speed cannot be controlled by varying the feed rate and that a larger crucible unit is required to contain the initial mixture.

More recent developments have centered on improving process economics. Automatic handling and weighing of the raw materials as well as finished metal and ferromolybdenum slag is one area of activity. Other activities center around the optimization of ingredient and consumable costs.55

Metallothermic mixtures used to produce ferromolybdenum are summarized in Table 5. Mixtures A – D represent different possibilities of increasing the reaction heat by using aluminum or calcium in the form of a calcium – silicon or a ferrosilicon aluminum alloy [43]. Reaction D can be regarded as a fairly typical ferromolybdenum reaction mix; it gives 87 kg ferromolybdenum with 67 – 73 % molybdenum, 0.05 – 0.08 % carbon, 0.03 – 0.05 % sulfur, 0.25 – 0.6 % silicon, and 5 kg remelt metal as well as a slag containing 0.34 % MoO_3, 13.85 % Fe_2O_3, 7.4 % CaO, 9.9 % Al_2O_3, and 64.5 % SiO_2. The reaction mix also contains recycled dust and metal remelt which is normal practice when continuously producing ferromolybdenum.

Mixtures E – G have been reported to have been used by Climax Molybdenum in their Langeloth (USA) plant [46]. The mixtures are based on 100 kg technical molybdenum oxide input with 85 % MoO_3 in the technical oxide. Reaction E can be regarded as a typical reaction mix for a ferromolybdenum with 58 – 64 % molybdenum. The maximum impurity levels quoted were 0.1 % carbon, 0.25 % sulfur, 0.5 % copper, and 1 % silicon. Reaction G can be regarded as a typical reaction mix yielding an approximately 70 % molybdenum alloy.

Mixtures H – J have been taken from literature from the former Soviet Union [48–50]. Mixture H gives ferromolybdenum containing 60 – 65 % molybdenum, 0.15 – 0.9 % silicon, 0.04 % phosphorus, 0.08 % sulfur, 0.05 % carbon, and ca. 0.5 % copper and slag containing 0.06 – 0.17 % molybdenum, 67 – 70 % SiO_2, 7 – 11 % FeO, 10 – 13 % Al_2O_3, 6 – 8 % CaO, and 1 – 3 % MgO. Mixture I uses a mix preheating to 150 °C, and should have resulted in a ferromolybdenum with ca. 56 % molybdenum (calculated). Mixture J is part of a calculated formulation according to Elyutin [50]. The calculation is based on 96.8 kg ferromolybdenum containing 58.14 % molybdenum, 0.53 % silicon, and 0.07 % carbon and 87 kg slag containing 65.65 % silicon oxide, 10.06 % aluminum oxide, and 24.28 % iron (II) oxide. A heat balance has been calculated for this formulation. The total heat generated is 422.45 MJ. This heat is assumed to be consumed to provide the latent and melting heat for the metal (25 %), the slag (50 %), and to cover the heat losses of 25 %.

7. Molybdenum Compounds

For molybdenum carbide, see → Carbides, Chap. 2.9.

7.1. Overview of Molybdenum Chemistry

As a transition element, molybdenum shows variable valency and forms many complexes and colored compounds. The outstanding feature of molybdenum is its chemical versatility: oxidation states from 2 − to 6 +; coordination numbers from 4 to 8 and, accordingly, a very varied stereochemistry; the ability to form compounds with most inorganic and organic ligands, with a particular preference for oxygen, sulfur, fluorine, and chlorine donor atoms; the formation of bi- and polynuclear compounds containing bridging oxide and chloride ligands and/or Mo – Mo bonds.

Molybdenum is very similar to tungsten, the third member of Group 6, but different from the first member, chromium. Molybdates(VI), unlike chromates(VI), are not strong oxidizing agents: much of the familiar chemistry of molybdenum is that of the 6 + and 5 + oxidation states.

In recent years research on molybdenum compounds has greatly increased because of their academic interest and their developing technical applications as lubricant additives (molybdenum disulfide and sulfur complexes), corrosion inhibitors, pigments, smoke suppressants, and heterogeneous catalysts (molybdenum trioxide and molybdates).

Recognition of the central role of molybdenum in a number of metalloenzymes (nitrogenase, nitrate reductase, xanthine oxidase) and the problem of molybdenum toxicity in ruminants have stimulated research in both molybdenum biochemistry and inorganic chemistry. The fact that molybdenum compounds are nontoxic to humans has lead to interest in the possibility of replacing compounds of toxic metals with safer molybdenum compounds, e.g., chromium in corrosion inhibitors, antimony in flame and smoke suppressants.

For more background information on molybdenum chemistry, see [51–56].

Compound Types. Typical compounds of molybdenum(VI) are the trioxide [*1313-27-5*], MoO_3; sodium molybdate [*7631-95-0*],Na_2MoO_4; and ammonium heptamolybdate, [*12054-85-2*], $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ and [*10102-40-6*], $(NH_4)_6Mo_7O_{24} \cdot 2H_2O$. These compounds are the starting points for the preparation of many other molybdenum compounds. The chemistry of the higher oxidation states (4^+ to 6^+) is dominated by oxomolybdenum cations, e.g., MoO^{2+}, $Mo_2O_4^{2+}$, $Mo_2O_3^{4+}$, MoO^{3+}, MoO_2^{2+} (see Section 7.6). The oxide ligands may be bound to just one molybdenum (terminal oxide) or to two

or more molybdenum atoms (bridging) [57]. Replacement of one or more oxide ligands by sulfide has produced many molybdenum – sulfur complexes and clusters [58], [59].

The higher halides are covalent, e.g., molybdenum hexafluoride [*7783-77-9*], MoF_6, and molybdenum pentachloride [*10241-05-1*], $MoCl_5$.

Compounds of molybdenum(II) and lower oxidation states are stabilized by unsaturated ligands such as carbon monoxide, e.g., in molybdenum hexacarbonyl [*13939-06-5*], $Mo(CO)_6$, and by molybdenum – molybdenum bonds, and so are bi- or polynuclear, e.g., molybdenum(II) acetate [*14221-06-8*], $Mo_2(CH_3COO)_4$, and molybdenum(II) chloride [*11062-51-4*], Mo_6Cl_{12}.

Preparative Chemistry. The starting point in preparative molybdenum chemistry is molybdenum(VI) oxide, MoO_3 (Fig. 11). Molybdenum disulfide, the naturally occurring form of molybdenum, is unreactive.

Figure 11. Relationship between some molybdenum compounds

Aqueous Solution Chemistry. The aqueous chemistry of molybdenum is complicated [52]. It is dominated by oxo species which are prone to dimerize or polymerize. Hydrated cations (i.e., cations having only water bound to molybdenum) are known only for oxidation states 2+ and 3+; they are powerful reducing agents which oxidize in air. The aqueous chemistry of molybdenum is summarized in Figure 12. The aqueous ion of molybdenum(IV) (not shown in Fig. 12) is the red trimer, $[Mo_3O_4(H_2O)_9]^{4+}$ [*74353-85-8*].

Figure 12. Aqueous chemistry of molybdenum showing species [52], reducing agents, and conditions
Reducing agents: a) Sodium dithionite, $Na_2S_2O_4$; b) Hydrazinium hydrate, $N_2H_4 \cdot H_2O$; c) Tin(II) chloride; d) Liquid mercury

Redox Chemistry. Molybdenum exemplifies the general trend of a transition metal group; the higher oxidation states of the heavier elements (molybdenum and tungsten) are more stable (resistant to reduction) and the lower oxidation states less stable (more prone to oxidation) than those of the first element (chromium). Reduction potentials are summarized in Figure 13 [60]. Note that reduction in water bypasses molybdenum(IV).

For the reduction of molybdate in neutral or alkaline solution, sodium dithionite is useful, e.g., in the preparation of the molybdenum(V) cysteine complex [*26998-42-5*], $Na_2[Mo_2O_4\{SCH_2CH(NH_2)COO\}_2] \cdot 5\,H_2O$ [61].

Molybdenum(III) solutions oxidize rapidly in air and must be handled under nitrogen or argon. With molybdenum(V), aerial oxidation is slow. Titration of reduced molybdenum solutions with cerium(IV) sulfate or permanganate

Figure 13. Reduction potentials (in volts) of molybdenum couples in acidic and alkaline aqueous solutions [60]
The more negative the potential, the more reducing is the couple, i.e., the more stable is the higher oxidation state.

is a volumetric method of determining molybdenum [62].

7.2. Molybdenum Oxides

Well characterized oxides are molybdenum trioxide, MoO_3, and molybdenum dioxide, MoO_2. Mixed-valency oxides and molybdenum blues are also important.

Molybdenum Trioxide. Molybdenum trioxide [*1313-27-5*], molybdenum(VI) oxide, MoO_3, M_r 143.95, is the ultimate product of the oxidation of molybdenum compounds. It forms white orthorhombic crystals that are photosensitive, i.e., turn blue in light. The compound is weakly paramagnetic and an *n*-type semiconductor. Other properties are listed in Table 6. It is produced by roasting molybdenum disulfide in air at 600 °C and may be purified by sublimation (see Section 4.2). It can also be prepared by reacting ammonium molybdate at 550 °C with oxygen or by precipitation from an aqueous ammonium molybdate solution treated with concentrated nitric acid [65].

The structure of molybdenum trioxide comprises layers built from linked, distorted MoO_6 octahedra. Crystal morphology depends on the method of preparation: needles occur after vapor condensation, platelets after crystal growth on silica or graphite [66]. Molybdenum trioxide has a characteristic IR spectrum showing Mo – O vibrations (996, 870, 821, and 570 cm^{-1}).

Molybdenum trioxide is an acidic oxide soluble in aqueous alkali and ammonia. Freshly precipitated MoO_3, which is much more reactive than the aged oxide, dissolves in aqueous solutions of citric, malic, and other hydroxycarboxylic acids [67], and in solutions of

ethylene glycol, glycerol, and other polyols to form molybdenum(VI) complexes [68]. Molybdenum trioxide also reacts with β-diketones (e.g., acetylacetone) to form complexes such as $MoO_2(CH_3COCHCOCH_3)_2$ [*17524-05-9*] which is a useful starting compound for preparing other molybdenum(VI) complexes by ligand exchange reactions. It is reduced by hydrogen at 500 – 600 °C to MoO_2 and at 900 – 1000 °C to molybdenum metal.

Molybdenum trioxide in combination with more basic metal oxides finds application in heterogeneous catalysis (see Section 7.5). Studies of MoO_3 specimens with different crystal habits have demonstrated structure sensitivity of MoO_3 selective oxidation catalysts; the type of reaction catalyzed depends on the predominant crystal face. Platelike crystallites predominantly expose the (010) face which is responsible for insertion of oxygen into allylic compounds; activation of, for example, propene occurs at the (100) and (101) faces, and total oxidation at all faces [66].

Hydrates of MoO_3. The monohydrate, $MoO_3 \cdot H_2O$ [*39082-25-2*], precipitates when a concentrated solution of sodium molybdate is acidified with hydrochloric acid. The dihydrate, $MoO_3 \cdot 2\,H_2O$ [*25942-34-1*], precipitates when a solution of ammonium heptamolybdate is acidified with nitric acid [65]; it is commonly referred to as molybdic acid ($H_2MoO_4 \cdot H_2O$). Both hydrates are yellow.

Molybdenum Dioxide. Molybdenum dioxide [*18868-43-4*], molybdenum(IV) oxide, MoO_2, M_r 127.95, is a dark blue crystalline solid and consists of chains of distorted MoO_6 octahedra. The distortions arise from Mo – Mo bonding leading to alternate long (0.31118 nm) and short (0.25106 nm) Mo – Mo distances [69], [70]. Properties are listed in Table 6. Molybdenum dioxide is a metallic conductor and is weakly paramagnetic. It is produced by reducing MoO_3 with hydrogen, ammonia, and carbon monoxide at 600 °C.

Molybdenum dioxide is a neutral oxide that is insoluble in acid and alkali. It reacts with chlorine giving dichlorodioxomolybdenum(IV) [*13637-68-8*], MoO_2Cl_2, and with carbon tetrachloride giving molybdenum tetrachloride [*13320-71-3*], $MoCl_4$.

Molybdenum Blues. Molybdenum blues [*66771-43-5*], so called because of their blue color, are mixed oxide – hydroxides of molybdenum(VI) and molybdenum(V) (see Fig. 12) [71]. They are amorphous solids that are soluble in water and alcohols. A typical species is $(Mo_3^{6+}Mo_3^{5+}O_{18}H)^-$ which has an absorption maximum at 450 nm.

The formation of molybdenum blues is the basis of a colorimetric method for determining phosphorus [72]. Molybdate and orthophosphate ions condense in acidic solution to give molybdophosphoric acid which is reduced by hydrazinium sulfate to a molybdenum blue with maximum light absorbance at 820 – 830 nm. The color intensity is proportional to the amount of phosphate incorporated. The reduced molybdophosphate is an example of a heteropoly blue [71].

Mixed Valency Oxides. The mixed Mo(VI) – Mo(V) oxides (molybdenum oxide bronzes) have an intense color and metallic luster [73].

The binary bronzes MoO_x (x between 2 and 3), constitute a series of deep blue or purple compounds. They are prepared by heating MoO_3 in vacuo or with molybdenum metal. The structures are built from edge- and corner-sharing $[MoO_6]$ octahedra, or $[MoO_6]$ octahedra and $[MoO_4]$ tetrahedra. The Magneli phases, Mo_4O_{11} [*12033-38-4*], and Mo_8O_{23} [*12058-34-3*] have metallic properties at room temperature.

The ternary oxides include the red bronzes, $A_{0.33}MoO_3$ (A = Li, K, Rb, Cs, Tl), which are semiconductors, the blue bronzes $A_{0.3}\,MoO_3$ (A = K, Rb, Tl), purple bronzes $A_{0.9}Mo_8O_{17}$ (A = Li, Na, K, Tl), and a rare-earth bronze $La_2Mo_2O_7$; they behave like metals at room temperature. Interest in these compounds is focused on their electrical and optical properties.

7.3. Molybdenum Chalcogenides

The most important chalcogenide of molybdenum is molybdenum disulfide, which is the principal source of molybdenum, in the form of the mineral molybdenite. Molybdenum selenide [*12058-18-3*], $MoSe_2$, and telluride [*12058-20-7*], $MoTe_2$, are also known.

Molybdenum Disulfide. Molybdenum disulfide [*1317-33-5*], molybdenum(IV) sulfide, MoS_2, M_r 160.07, is a black crystalline solid that occurs in two forms: hexagonal, which is found in the mineral molybdenite [*1309-56-4*] and rhombohedral (Table 7). The solid is diamagnetic and a semiconductor. It is built of S−Mo−S layers whose sulfur atoms are in contact (Fig. 14). Within each layer molybdenum is at the centre of a trigonal prism of sulfur atoms. Since the forces operating between the layers are weak van der Waals attractions, the layers can slide over one another giving molybdenum disulfide a slippery texture and solid-state lubrication properties like graphite.

∗ Standard enthalpy and free energy of formation from the elements and entropy at 298.15 K [63], [64], [74].

The hexagonal form is produced by heating molybdenum with sulfur, ammonium tetrathiomolybdate [$(NH_4)_2MoS_4$], or molybdenum trisulfide at 1100 °C. The compound is amorphous at 250 – 400 °C; crystallization requires prolonged heating at 1100 °C. The rhombic form is obtained by heating the hexagonal form in vacuo at 7.5 GPa and 1200 °C, or by reacting MoO_3 with sulfur and potassium carbonate at 1100 °C.

Molybdenum disulfide dissolves only in strongly oxidizing acids (e.g., aqua regia) to give molybdenum(VI) compounds. When heated in vacuo at 1200 °C it decomposes to Mo_2S_3 and metallic molybdenum. Heating in air at 500 °C produces MoO_3. Reduction with hydrogen at 1100 °C or > 1500 °C yields Mo_2S_3 or molybdenum metal, respectively.

Molybdenum Sesquisulfide. Molybdenum sesquisulfide [*12033-33-9*], dimolybdenum trisulfide, molybdenum(III) sulfide, Mo_2S_3, M_r 288.08, has a different structure from MoS_2; the molybdenum is at the center of a distorted octahedron of sulfur atoms. Molybdenum sesquisulfide is a grey solid and is prepared by heating molybdenum and sulfur (2 : 3) in vacuo at 1400 °C. It dissolves in, and is oxidized to molybdenum(VI), by aqua regia. In air at 350 °C it oxidizes to molybdenum trioxide. Hydrogen at 1500 °C reduces it to molybdenum metal.

Molybdenum Trisulfide. Molybdenum trisulfide [*12033-29-3*], molybdenum(VI) sulfide, MoS_3, M_r 192.14, is the sulfide precipitated in conventional inorganic analysis when hydrogen sulfide is passed through an acidified molybdate solution. Molybdenum trisulfide, like the sulfides of tin, arsenic and antimony, dissolves in yellow ammonium sulfide giving a tetrathio salt, MoS_4^{2-}.

According to X-ray absorption spectroscopy, the composition MoS_3 corresponds to $Mo(S^{2-})_2(S_2^{2-})_{0.5}$, one third of the sulfur is disulfide (S_2^{2-}); the formal oxidation state of the molybdenum is 5^+ [75].

When heated in nitrogen at ca. 350 °C molybdenum trisulfide decomposes to amorphous molybdenum disulfide. Heated in air, it begins to oxidize to molybdenum trioxide at 200 °C.

Chevrel Phases. The Chevrel phases are ternary molybdenum chalcogenides, $M_xMo_6X_8$ (where M is a metal and X a chalcogenide), for example, $PbMo_6S_8$ [*39432-49-0*] [76]. They are black powders prepared by heating the constituent elements in vacuo at 1000 °C. They consist of linked [Mo_6S_8] clusters having sulfur atoms at the corners of a cube and molybdenum atoms at the face centers (the same structure as the [Mo_6Cl_8] structure, see Section 7.4). These compounds have attracted great interest as superconductors with critical temperatures as high as 15 K and as battery materials.

Ammonium Tetrathiomolybdate. Ammonium tetrathiomolybdate [*15060-55-6*], $(NH_4)_2[MoS_4]$, M_r 260.28, crystallizes from

Figure 14. Computer-drawn structure of molybdenum disulfide
A) Side view showing the S – Mo – S layers; B) Top view of a hexagonal fragment of one layer

a solution of ammonium molybdate saturated with hydrogen sulfide to form deep red crystals. The $[MoS_4]^{2-}$ ion is tetrahedral and is the thio analogue of molybdate. Ammonium tetrathiomolybdate has an extensive chemistry and is an entry point to much molybdenum – sulfur chemistry. The sulfur atoms form bridges to metal ions so forming clusters, e.g., the species $[S_2MoS_2CoS_2MoS_2]^{2-}$ with Co^{2+} [52].

7.4. Molybdenum Halides

Binary halides are known for molybdenum in oxidation states (II) to (VI). The preparation of molybdenum fluorides and chlorides is summarized in Figure 15. The only molecular halide is molybdenum hexafluoride, MoF_6, which is a volatile liquid. The coordination number of molybdenum is six in the halides of Mo(V), (IV), and (III), the molybdenum atoms being linked by bridging halogens.

Molybdenum(II) chloride is an extended solid containing $[Mo_6Cl_8]^{4+}$ clusters linked by bridging chlorines so giving the formula Mo_6Cl_{12}. In the cluster eight chlorine atoms are at the corners of a cube. Molybdenum atoms, linked by Mo − Mo bonds, are at the face centers of the cube and so constitute an octahedral Mo_6 cluster. The cluster is very stable both to hydrolysis and oxidation and persists through many reactions.

A feature of the halides of Mo(IV), (III), and (II) is the formation of bonds between molybdenum atoms. Consequently, there is pairing of electron spins on adjacent molybdenum atoms and so the magnetic moments of the halides are less than the spin-only values.

Molybdenum Pentachloride. Molybdenum pentachloride [*10241-05-1*], molybdenum(V) chloride, $MoCl_5$, M_r 273.21, is the most important molybdenum halide. The dark green – black crystals (*mp* 194 °C) consist of Mo_2Cl_{10} dimers; the vapor and solutions contain $MoCl_5$ monomers.

Molybdenum pentachloride is soluble in carbon tetrachloride, benzene, and many other organic solvents. It is very reactive, undergoing hydrolysis in air, water, and damp organic solvents to form brown oxomolybdenum(V) chlorides. It is supplied and stored in sealed ampoules and must be handled under argon or nitrogen or in vacuo.

The outstanding property of molybdenum pentachloride is its ability to abstract an oxygen atom from water, sulfur dioxide, triphenylphosphine oxide (Ph_3PO), dimethyl sulfoxide (Me_2SO), and other oxygen-containing compounds to form oxomolybdenum complexes,

$MoOCl_3A_2$, (e.g., A = Ph_3PO, Me_2SO). In concentrated hydrochloric acid molybdenum pentachloride forms the deep green complex ion $[MoOCl_5]^{2-}$.

Molybdenum pentachloride is the starting point for much nonaqueous and organomolybdenum chemistry.

Figure 15. Preparation of molybdenum fluorides and chlorides

Oxomolybdenum Halides. In oxidation states 5+ and 6+ molybdenum has a strong tendency to form multiple bonds to oxygen. The oxomolybdenum halides are volatile solids which may be sublimed in vacuo. They are more stable than the binary halides and are formed when the binary halides are exposed to air and water.

Oxomolybdenum(VI) compounds are of two types: $MoOX_4$ (X = F, Cl), and MoO_2X_2 (X = F, Cl, Br). Oxomolybdenum(V) compounds are generally monoxo, e.g., $MoOCl_3$.

Trichlorooxomolybdenum(V). Trichlorooxomolybdenum(V) [*13814-74-9*], $MoOCl_3$, M_r 218.30, is a green solid consisting of octahedral $[MoOCl_5]$ units linked through cis-chlorine atoms. It forms adducts with many organic ligands, e.g., $MoOCl_3 \cdot L$ (L = ligand) with acetylacetone and 2,2′-bipyridyl, and $MoOCl_3 \cdot 2\,L$ with diethyl ether and pyridine.

7.5. Molybdates, Isopolymolybdates, and Heteropolymolybdates

Sodium molybdate and other simple molybdates contain the tetrahedral $[MoO_4]^{2-}$ ion. Ammonium heptamolybdate (an isopolymolybdate), $(NH_4)_6Mo_7O_{24} \cdot 4\,H_2O$, is composed of linked, distorted $[MoO_6]$ octahedra. In the heteropolymolybdates, molybdenum and another element are present in the same structure. The properties of some of the more important molybdates are summarized in Table 8.

Ammonium and Alkali-Metal Molybdates. Ammonium and alkali-metal molybdates are soluble in water (Table 8). They are made by crystallizing or evaporating solutions of molybdenum trioxide dissolved in aqueous alkali. Ammonium dimolybdate is used as an intermediate for purifying technical-grade MoO_3 (see 4.2). For the production of sodium molybdate, see 4.2.

Ammonium molybdates are made by dissolving MoO_3 in aqueous ammonia solution; $(NH_4)_2MoO_4$ then crystallizes from aqueous ammonia, $(NH_4)_6Mo_7O_{24} \cdot 4\,H_2O$ from a solution kept at the boiling point for 1 h, and $(NH_4)_2Mo_8O_{26} \cdot 5\,H_2O$ from an acidified aqueous solution of $(NH_4)_6Mo_7O_{24} \cdot 4\,H_2O$. The dimolybdate, $(NH_4)_2Mo_2O_7$, may be crystallized from hot ammoniacal molybdate solutions.

The structures of the isopolymolybdates are based on linked, distorted $[MoO_6]$ octahedra. The structure of ammonium dimolybdate consists of infinite chains of pairs of edge-shared $[MoO_6]$ octahedra with adjacent pairs linked by $[MoO_4]$ tetrahedra [79].

Ammonium di- and heptamolybdates are used as sources of water-soluble molybdenum, for example, in the preparation of catalysts. When the catalyst is calcined, the molybdate decomposes to molybdenum trioxide and ammonia.

Molybdates of Di- and Trivalent Cations. Molybdates of divalent cations (except Mg^{2+}) are insoluble in water (Table 8). They are prepared by precipitation from a sodium or ammo-

Table 8. Properties of some molybdates [53], [77]

Molybdate	M_r	Structure [a]	Color	Solubility in water, wt % [b]	ΔH_f°, kJ/mol [c]
$(NH_4)_2MoO_4$	196.01	4	white	39	
$(NH_4)_2Mo_2O_7$	339.95	4 or 6		30	
$(NH_4)_6Mo_7O_{24}$ $\cdot 4H_2O$	1235.8	6	white	30

[a] Coordination of the countercation (except ammonium) by oxide and coordination of molybdenum (4 = tetrahedral; 6 = octahedral).
[b] Weight percent of anhydrous salt in 100 g saturated solution at 25 °C.
[c] Standard heat of formation from the elements at 298.15 K.
[d] Two polymorphs: low-temperature form, b, transforms to the high-temperature form, a, at 400 °C [78].

nium molybdate solution or by heating mixed solid oxides. The coordination environment of the molybdenum may be tetrahedral or octahedral.

Molybdates of trivalent cations have the formula $A_2(MoO_4)_3$ or $A_2Mo_3O_{12}$, with A = Al, Cr, Fe, Bi, lanthanide. Coordination of the molybdenum is tetrahedral; the other cation is usually octahedral.

A number of these molybdates have important uses. Cobalt, iron, and bismuth molybdates are catalysts for the selective oxidation of organic compounds (see Section 8.1): olefins are oxidized to unsaturated aldehydes and ketones, e.g., propene to acrolein (cobalt and bismuth), propene and ammonia to acrylonitrile (bismuth), methanol to formaldehyde (iron). Molybdenum is the source of selectivity in these reactions. The first step is generally activation of a C – H bond over the more basic (nonmolybdenum) oxide and the molybdenum then controls oxygen insertion. The well known Co–Mo/alumina hydrodesulfurization catalyst does not, however, strictly contain cobalt molybdate.

Other actual or proposed applications are: calcium and strontium molybdates doped with neodymium as lasers; lanthanide molybdates for optical and optoelectric applications; zinc molybdate as a white pigment and corrosion inhibitor.

Heteropolymolybdates. The heteropolymolybdates consist of $[MoO_6]$ octahedra incorporating atoms of a different element, the heteroatom [52], [80]. The heteroatoms are completely surrounded by the oxygen atoms of the $[MoO_6]$ octahedra. The resulting coordination of the heteroatom may be tetra- or octahedral. The 12-molybdo species, $[X^{+n}Mo_{12}O_{40}]^{(8-n)-}$, is an important group with tetrahedrally coordinated heteroatoms (X). An example is 12-molybdophosphoric acid [*12026-57-2*], $H_3[PMo_{12}O_{40}] \cdot 28\,H_2O$, prepared by dissolving molybdenum trioxide in phosphoric acid; it is yellow and readily soluble in water. Ammonium 12-molybdophosphate, which precipitates when ammonium molybdate is added to a solution of disodium hydrogen phosphate, is used for the gravimetric determination of phosphate [76]. The phosphomolybdates are selective oxidation catalysts, e.g., in the conversion of acrolein to acrylic acid [81].

7.6. Other Molybdenum Compounds

Molybdenum forms a large number of coordination compounds or *complexes* [52]. Complexes with organosulfur ligands attract a great deal of interest because of their significance in molybdenum biochemistry (see Section 7.1) and applications as oil-soluble antiwear and friction-reducing additives [82]. Examples of the latter are phosphorodithioates (dithiophosphates) and dithiocarbamates, $[Mo_2O_3L_4]$ and $[Mo_2O_2S_2L_2]$ where L is $(RO)_2PS_2^-$, $R_2NCS_2^-$.

Molybdenum hexacarbonyl [*13939-06-5*], $Mo(CO)_6$, M_r 264.002, *mp* 150 °C, *bp* 156.4 °C (sublimes), is a white, air-stable solid that is insoluble in water but soluble in organic solvents. It is made from molybdenum pentachloride (see Fig. 11) and is commercially available. It is a starting point for the synthesis of low-valent and organomolybdenum compounds [83]. The structure consists of CO groups octahedrally disposed around molybdenum and bound through carbon.

8. Uses of Molybdenum Compounds

8.1. Catalysis

Molybdenum-containing catalysts are used for a broad range of reactions [90] (see also → Heterogeneous Catalysis and Solid Catalysts). In some cases, the catalyst is a single molybdenum compound, and either soluble (homogeneous) or insoluble (heterogeneous) in the reaction medium. In other cases, the catalyst is a binary mixture of the oxides and/or sulfides of molybdenum and of another element (usually Co, Ni, Fe, W, or Bi). The catalytic properties of these binary compositions differ greatly from those of the individual compounds. The heterogeneous catalysts are often formed and supported on a substrate such as activated alumina, silica, carbon, or zeolite. The support can greatly improve catalyst activity, selectivity, and mechanical strength. In industrial practice other elements or compounds (e.g., potassium, phosphorus, tungsten, or silica) are often added to the binary compositions as additives to further enhance activity, selectivity, and strength.

The scope and versatility of molybdenum catalysts are illustrated in Table 9 [91]. The activity and selectivity of catalysts based on MoO_3 and MoS_2 are summarized for redox reactions, isomerization, polymerization, addition, and decomposition (usually classified as acid – base reactions).

One of the largest uses for molybdenum catalysts is in the desulfurization of petroleum, petrochemicals, and coal-derived liquids, in which organosulfur compounds react with hydrogen at the catalyst surface and sulfide ions are removed as hydrogen sulfide. Desulfurization is used to improve product color, smell, and stability, to eliminate sulfur dioxide emission on fuel combustion, and to make possible subsequent reforming processes which may use sulfur-sensitive catalysts. Today, environmental air quality is a major reason for desulfurization.

The most common desulfurization catalyst is a binary mixture of cobalt oxide and an excess of molybdenum trioxide on an activated alumina substrate. After being charged into the industrial reactor, the catalyst reacts with the sulfur-containing reducing atmosphere to form molybdenum and cobalt sulfides as the working catalyst.

A major development in the history of hydrocarbon oxidation was the discovery of bismuth molybdate catalysts for the partial oxidation and ammoxidation of propene to acrylonitrile in one step [92].

$$CH_2{=}CHCH_3 + NH_3 + 1\,1/2\,O_2 \rightarrow CH_2CHCN + 3\,H_2O$$

The original catalyst was reported to have a composition of 50 % $Bi_9PMo_{12}O_{52}$ and 50 % SiO_2, with the silica gel support preventing catalyst disintegration in the fluidized bed operation. This catalyst and its modifications account for virtually all of the acrylonitrile production in the world.

Another major catalyst based on ferric molybdate ($5\,MoO_3 \cdot Fe_2O_3$) is used to selectively oxidize methanol to formaldehyde (→ Formaldehyde, Chap. 4.2.) [93]:

$$CH_3OH + 1/2\,O_2 \rightarrow CH_2O + H_2O$$

Molybdenum catalysts are also important in commercial coal liquefaction processes where coal is converted into upgraded liquid fuels. Coal liquefaction processes commonly utilize either alumina-supported cobalt molybdate or molybdenum trioxide as catalyst to effect desulfurization, denitrogenation, deoxygenation, cracking, and hydrogenation.

Table 9. Reactions catalyzed by molybdenum oxides and sulfides [91]

Type of reaction	Example	Catalyst	Temperature range, °C	Conversion, %	Selectivity, %
Reactions with molecular hydrogen					
Isotopic exchange	$H_2 + D_2 \rightarrow 2\,HD$	$MoO_3/Al_2O_3-SiO_2$	80		very high
Hydrogenation	benzene → cyclohexane	MoO_3	420–450	60	
	acetylene → ethylene	MoO_3-CoCl_2/SiO_2	260–300		100
	naphthalene → decalene	MoS_2	340		yield 77
	sulfur → hydrogen sulfide	MoS_2	200	100	
	selenium → hydrogen selenide	MoS_2	330–350	100	
	maleic anhydride → succinic anhydride	$CuMoO_4/SiO_2$	120–160	100	
Hydrogenolysis	α- and β-methyl naphthalene → naphthalene + methane	$CoO-MoO_3/Al_2O_3$			yield 40
	ethylcyclohexane → products	MoO_3/Al_2O_3	510		
Reduction	phenol → benzene + H_2O	MoS_2	350		yield 88–98
	thiophenol → benzene + H_2S	MoS_2	200	100	
	thiophene → $C_4H_{10} + H_2S$ C_4H_8 C_4H_6	MoS_2	300	98	
	organic sulfur compounds → hydrocarbons	$CoO-MoO_3/Al_2O_3$	225–425		
Reactions with molecular oxygen					
Selective oxidation	propene → acrolein	$Bi_2O_3-MoO_3$	450	95	95
	butene → maleic anhydride	$CoO-MoO_3-P_2O_5/$			
SiO_2	450	76	50		
	benzene → maleic anhydride	$V_2O_5-MoO_3-P_2O_5/$			
Al_2O_3	425–450		85		
	o-xylene → phthalic anhydride	$V_2O_5-MoO_3$	400		48
Oxidation of functional groups	methanol → formaldehyde	$Fe_2(MoO_4)_3$	300–400	92	92
	acrolein → acrylic acid	$CoO-MoO_3-TeO_2$	383	85	65
Oxidative condensation	propene + NH_3 → acrylonitrile	$Bi_2O_3-MoO_3$	400–500		yield 80
	toluene + NH_3 → benzonitrile	$V_2O_5-MoO_3/Al_2O_3$	415		yield 94
Oxidative dehydrogenation	butene → butadiene	$Bi_2O_3-MoO_3$	370–550		90
	ethylbenzene → styrene	MoO_3-MgO	420–450		82–84
Oxyhydration	propene → acetone	SnO_2-MoO_3	135		85
Oxidative dehydrocondensation	*n*-butane + SO_2 → thiophene	MoO_3/Al_2O_3	595	70	44
	butene + H_2S → thiophene	$CoO-MoO_3/Al_2O_3$	570		yield 37
Oxidation with other oxidants					
Epoxidation	propene + H_2O_2 → propylene oxide	MoO_3 in H_2O_2 and pyridine	60	80	100
Isomerization					
Structural isomerization	*n*-pentane → isopentanes	MoO_3/Al_2O_3	425–450	50	95
Ring contraction	cyclohexane → methylcyclopentane	MoO_3/Al_2O_3	455–495		yield 37
Disproportionation					
Olefin metathesis	propene → butene + ethylene	MoO_3/Al_2O_3	66–288	43	94
Polymerization					
Polymerization	ethylene → polyethylene	MoO_3/Al_2O_3	200–260	50	
	acetylene → benzene	$CoO-MoO_3/Al_2O_3$	62	98	100
Etherification					
Formation of complex ethers	succinic acid + hexanol → ether	MoS_2/carbon	130–220	45–97	100
Addition					
Addition to C=C	allylic alcohol + H_2O_2 → glycerol	MoO_3 in acetic acid	70–100		
Decomposition					
Dehydration	2-propanol → propene	MoO_3	191–224		100
	ammonium benzoate → benzonitrile	MoO_3	225–245		
Dehydrogenation	ethylbenzene → styrene	MoS_2	414		yield 94
	cyclohexane → benzene	MoO_3/Al_2O_3	500		yield 63
Dehydrocyclization	*n*-heptane → toluene	MoO_3/Al_2O_3	450–500		yield 75
Dehydrocondensation	isobutene → xylenes	MoO_3/Al_2O_3	200		yield 90

Phosphomolybdate compounds are acidic oxidants and are used in both homogeneously and heterogeneously catalyzed processes such as the hydration of propene in liquid phase and the oxidation of isobutyric acid to methacrylic acid.

Molybdenum hexacarbonyl is a versatile homogeneous and heterogeneous catalyst. It is widely used in the production of methanol from carbon monoxide, to effect olefin metathesis, desulfurization, aqueous coal liquefaction, and epoxidation.

8.2. Lubrication

Molybdenum disulfide is an important solid lubricant, being used primarily to reduce wear, friction, and sustain lubrication under boundary sliding conditions (→ Lubricants and Related Products). It is a black powder that is insoluble in ordinary aqueous and organic solvents but dissolves by complex formation in potassium cyanide, and reacts with strong oxidizing agents such as aqua regia or hot concentrated sulfuric acid to give hexavalent molybdenum species. It is an excellent high-temperature lubricant which is stable in vacuo or an inert atmosphere to 1200 °C, and to about 350 °C in air.

The primary commercial source for MoS_2 is the mineral molybdenite, from which > 98 % pure powder is recovered and purified using oil flotation and other techniques (Chap. 4) with carbon being the major impurity. The lubricating powder is available in several grades based on its median particle size which may range from ca. 1 to 40 µm.

The crystal structure of natural MoS_2 is hexagonal (Fig. 14). Its excellent intrinsic lubricating properties are attributed to the wide spacing and weak van der Waals bonding between the S – Mo – S sandwich layers, and to the net positive charge on the surface which promotes easy shear by means of electrostatic repulsion [94]. This intrinsic lubricating quality contrasts with graphite, which requires the presence of condensable vapors (e.g., from water or hydrocarbons) to promote crystal cleavage and low friction [95].

The fundamental and practical aspects of MoS_2 lubrication are reviewed in [87], [96], [97]. Molybdenum disulfide is sometimes simply rubbed on surfaces as a thin film to provide short-term lubrication. As an additive, it enhances the performance of other lubricants like grease or oil. It can also be incorporated into paint-like coatings for longer service life. Finally, it can be incorporated into plastics, rubber, and powder metal matrices as an alternative to conventional lubricants to impart lifetime self-lubrication.

Summaries have been published describing the use of MoS_2 in greases [98], rubber [99], bonded coatings [100], and motor oils [101].

The largest consumption of MoS_2 is in *greases* used in mining, manufacturing, and transportation [98]. In greases, 1 – 20 wt % molybdenum disulfide gives added protection from wear and galling, and provides back-up lubrication should the grease deplete or thermally degrade. Pastes composed of grease and containing 20 –60 wt % MoS_2 are used with open gears, universal joints, spline drives, and in metal forming, press-fitting and various wear-in operations. They have outstanding boundary lubrication behavior which prevents fretting, galling, and seizing.

As an extra-fine powder, MoS_2 (0.5 – 1 wt %) is suspended in *industrial oils, motor oils, and synthetic fluids*, with the aid of chemical dispersants such as polyethylene where it behaves as an extreme-pressure and antiwear additive. In motor oils, it also improves vehicular fuel economy.

Paint-like coatings containing 30 – 85 vol% MoS_2 in either an organic or inorganic silicate binder are used on fasteners, machine tools, forklift chains, door locks, chutes, and sliding parts of office equipment to reduce friction and wear. Temporary coatings of MoS_2 in water-soluble binders (e.g., poly(vinyl alcohol) and polyacrylates) are used in die casting as a mold release, and in metal forming operations such as ironing, wire drawing, and extrusion.

In *plastic, rubber, and powdered metal compositions,* 0.5 – 4 wt % MoS_2 imparts self-lubricating behavior obviating the requirement for externally applied lubrication. These materials are used in articles such as cams, thrust washers, ball bearing retainers, compressor piston rings, sheaves, gears, conveyor belting, and dynamic seals.

Molybdenum disulfide is not the only molybdenum compound used in lubrication. *Oil-soluble molybdenum–sulfur compounds* have also long been used as antiwear and extreme-pressure additives in lubricating oils and greases [102]. Commercial oil-soluble additives are compositions based on tetrathiomolybdates and complexes of molybdenum with xanthates, dithiocarbamates, dithiophosphates, diketones, dithiols, and dimercaptothiadiazoles [102].

8.3. Corrosion Inhibition (→ Corrosion)

In 1939, two patents first described the use of readily soluble sodium, potassium, and ammonium molybdates as corrosion inhibitors for motor vehicle engine coolants [103], [104]. These and other inorganic molybdates are now among the most popular corrosion inhibitors because of their favorable properties and behavior. Molybdate is an anodic inhibitor, i.e., it inhibits by increasing the polarization of the anode component of the metal corrosion cell. It does this by precipitating escaping metal cations as molybdate species to block anodic sites and strengthen developing metal oxide films. Molybdate inhibits the corrosion of more ferrous and nonferrous metals over a wider pH range than any other inhibitor apart from chromate. Unlike chromate, however, the simple molybdate anion is not an oxidant and thus can be used with chemicals and systems that do not tolerate the strongly oxidizing chromate. Of even greater importance, molybdate has a very low toxicity. The toxicity, environmental aspects, behavior, mechanistic studies, and many applications of the molybdates are reviewed in [105], [106].

Molybdates are seldom used alone – as with other anodically active inhibitors, molybdate efficacy is improved and its concentration requirement significantly reduced when it is combined with other inhibitors. The most widely employed synergists of molybdate inhibition are the cathodically active compounds, especially zinc salts (e.g., zinc sulfate). Other synergists are the oxidizing inhibitors (e.g., nitrite) and the filming inhibitors (e.g., amine phosphonates and hydroxyfatty acids) [106]. Filming inhibitors strongly adsorb to the metal surface and protect it from attack.

Sodium molybdate is a component of many of the factory-fill and after-market engine coolants used in the United States, Europe, and Japan. A modern engine coolant concentrate formulation containing molybdate and other inhibitors is as follows [107] (concentrations in weight percent):

Ethylene glycol	95.56
Sodium nitrate	0.10
Sodium molybdate dihydrate	0.20
Sodium tetraborate pentahydrate	0.40
Sodium silicate solution N*	0.30
Phosphoric acid 85 %	0.15
Sodium mercaptobenzothiazole, 50 % solution	0.50
Sodium tolyltriazole, 50 % solution	0.20
Sodium hydroxide	0.235
Water	2.30
Polyglycol	0.05
Dye	0.005

∗ Registered trademark of PQ Corp., Valley Forge, Pennsylvania.

The largest consumption of molybdates for corrosion inhibition is in the treatment of cooling water in open and closed recirculating cooling systems. Open systems include cooling tower waters associated with power generation, manufacturing operations, and with metals production and chemicals processing. A formulation of a corrosion inhibition treatment in an open cooling tower system (milligrams per liter) follows:

1-hydroxyethylidene-1,1-diphosphonic acid, 60 % solution	10
Sodium molybdate dihydrate	10
Zinc sulfate monohydrate	2
Sodium tolyltriazole, 50 % solution	2

Closed loop waters are used in stationary power engines, in refrigeration and humidity control, and in chilled-water air conditioning; a formulation of a corrosion inhibition treatment for a closed chilled-water air conditioning system (milligrams per liter) follows:

Sodium molybdate dihydrate	150
Sodium nitrite	150
Sodium tolyltriazole, 50 % solution	4

Not only the highly soluble sodium, potassium, lithium, and ammonium molybdate salts are used in corrosion inhibition; the very slightly soluble zinc, strontium, and calcium molybdates are effective corrosion-inhibiting pigments in

primer paints for steel and aluminum [108]. The pure compounds are no longer used; they have been replaced by equally and, in some cases, more effective pigments made by precipitating the pure compounds on less expensive, synergistic core materials such as zinc oxide, calcium carbonate, talc, or zinc phosphate [109–111].

Other products and processes which utilize molybdates as corrosion inhibitors include water-based hydraulic and metalworking fluids, lithium halide refrigerating brines, boiler waters, hot forging lubricants, aluminum anodizing processes, coal – water slurries, temporary rust-preventive coatings, rinses for phosphate conversion coating, oil field drilling muds, brake linings, water used for quenching after heat treatment, paint-spray water curtains, wet ball milling of ores, salt brines for ice-making, passivation treatments for galvanized zinc and tin plate, packaging paper and board used for metal parts, temporary coating of aluminum to prevent staining by water during storage and transport, and as a pitting inhibitor for stainless steels in mineral acids. These and other applications are reviewed in [106].

8.4. Flame Retardancy and Smoke Suppression

Treatments based on molybdenum compounds exhibit both flame retardancy and smoke suppression; they are particularly effective smoke suppressants for synthetic polymers.

In the early 1930s, heteropolymolybdates were found to act as flame retardants for wood [112]. Some 15 years later, ammonium heptamolybdate and sodium molybdate were shown to retard the flammability of cotton fabric, although the treatment was not durable to laundering [113]. Other molybdenum compounds were subsequently used as additives to suppress the flammability and smoke output of plastics [nylon, poly(vinyl chloride), poly(vinylidene chloride), polyesters, and epoxy resins] [114].

The following molybdenum compounds are effective flame retardants and smoke suppressants for both rigid and plasticized poly(vinyl chloride) and halogenated polyester systems [115]:

- Molybdenum disulfide [*1317-33-5*], MoS_2
- Molybdenum(VI) oxide [*1313-27-5*], MoO_3
- Ammonium dimolybdate(VI)(2-) [*27546-07-2*], $(NH_4)_2Mo_2O_7$
- Ammonium heptamolybdate(VI)(6-)-4-water [*12027-67-7*], $(NH_4)_6Mo_7O_{24} \cdot 4\,H_2O$
- Ammonium octamolybdate(VI) (4^-) [*12411-64-2*], $(NH_4)_4Mo_8O_{26}$
- Sodium molybdate(VI) [*7631-95-0*], Na_2MoO_4
- Calcium molybdate(VI) [*7789-82-4*], $CaMoO_4$
- Zinc molybdate(VI) [*13767-32-3*], $ZnMoO_4$
- Copper molybdate(VI) [*13767-34-5*], $CuMoO_4$
- Nickel molybdate(VI) [*12673-58-4*], $NiMoO_4$
- Iron(III) molybdate(VI) [*13769-81-8*], $Fe_2(MoO_4)_3$

Flame retardancy in these compounds is linked to the accelerated loss of halogen; their smoke retardancy depends on increased char formation [116].

Molybdenum trioxide and extended proprietary zinc and calcium molybdate compositions are employed as flame retardants in the above-mentioned plastics that are used in the building, transportation, and wire and cable industries.

8.5. Pigments

Sodium molybdate [*7631-95-0*] is the usual starting material for the production of inorganic molybdate chrome pigments (→ Pigments, Inorganic) and a number of organic pigments (toners) based on cationic or basic dyes. Small amounts of sodium molybdate are also used as a condensation catalyst for phthalocyanine pigments as well as to fix and shade the coloring of furs and hair with azines and the amino- and hydroxy-substituted aromatic compounds used for red – brown shades.

Inorganic Pigments. Molybdate chrome pigments (molybdenum orange [*12656-85-8*]) are generally considered to be modified lead chrome pigments, i.e., compounds of lead chromate and mixed lead chromate and sulfate whose hues range from lemon yellow to primrose. Molybdate chrome pigments exhibit bright

red – orange to bright yellow – red hues with the redder hues containing more molybdenum. Molybdate orange pigments are mixed tetragonal crystals whereas the lead chrome pigments form monoclinic and rhombic crystals.

Molybdate chrome pigments are made by coprecipitating lead chromate, molybdate, and sulfate from lead nitrate solutions with sodium chromate, molybdate, and sulfate solutions. The stoichiometry and conditions of precipitation are adjusted to determine the hue. Lead molybdate is itself white, but in the coprecipitated product it distorts the monoclinic lead chromate crystals sufficiently to produce the tetragonal form.

The molybdate chrome pigments exhibit clean colors, good tinctorial and hiding properties; are nonbleeding and soft-grinding; have high heat resistance, and better film gloss and light fastness than lead chrome. They are often used with organic pigments to supply needed hiding power.

Molybdate chrome pigments are more expensive than the lead chromes, but are preferred in many applications for their reddish hue, cleanliness and brightness of color. They are employed in paints, plastics, rubber, and often in printing inks where their opacity, low cost, and heat stability are advantages over organic red pigments.

Organic Pigments. Sodium molybdate is also used in the production of organic pigments. Organic pigments have a higher tinctorial strength and brightness than inorganic pigments, but their thermo- and photochemical stabilities are lower and they are more transparent and expensive. Their biggest single use is in the coloring of plastics.

Molybdenum compounds are used in the production of toners derived from cationic or basic dyes that have free or substituted amino groups. The most important dyes are:

Diphenylmethane	Auramine	C.I. 655
Triarylmethane	Malachite Green	C.I. 657
	Brilliant Green	C.I. 662
	Rhoduline Blue 6G	C.I. 658
	Acronol Brilliant Blue	C.I. 664
	Methyl Violet B	C.I. 680
	Victoria Pure Blue BO	C.I. Pr198
Xanthene	Rhodamine B	C.I. 749
	Rhodamine 6G	

The dyes are made into pigments (i.e., insolubilized) by replacing the simple anions (chloride and sulfate) with a heteropolymolybdate acid salt, such as 12-molybdophosphate, $[PMo_{12}O_{40}]^{3-}$. This acid salt is formed from disodium phosphate and sodium molybdate in the presence of a strong mineral acid (e.g., HCl). The commercial phosphomolybdate pigments or toners are collectively known as PMA colors. The heteropolymolybdate complexes with the basic dye may contain 1 mol P_2O_5 with from 12 to 24 mol MoO_3 as either the free acids or acid sodium salts. Pigments made with combinations of both phosphotungstate (PTA) and phosphomolybdate are known as PTMA colors. The PTMA colors show better fastness than either the PMA or PTA colors, but are also generally costlier.

8.6. Agriculture

Molybdenum is an essential trace element for enzymes which fix nitrogen in leguminous crops. Sodium molybdate is used as a soil additive in areas where natural molybdenum is deficient and plant growth suffers. It is usually applied as part of fertilizer or seed treatments. About 0.25 kg molybdenum per acre (0.62 kg/ha) may be used.

9. Analysis

Molybdenum can be determined by gravimetric, volumetric, and colorimetric methods [117]. As long as great accuracy is not required, the most satisfactory method is, however, atomic absorption spectroscopy.

Atomic Absorption Spectroscopy. The absorption lines used and the achievable sensitivities in atomic absorption spectroscopy are shown in Table 10. Sensitivity may be increased by using a three-slot burner or by inert gas separation of the flame. Interference due to the presence of calcium, strontium, manganese, iron, and sulfate is reported to be eliminated in the presence of large amounts of aluminum [121] or 2 % ammonium chloride [118].

Table 10. Atomic absorption spectroscopic analysis for molybdenum

Absorption line, nm	Sensitivity, ppm/1 % abs**	Reference
313.26	0.8	[118], [119]
313.26*	0.4	[120]
317.03	1.1	[118]
379.83	1.3	[118]
319.40	1.4	[118]
386.41	1.7	[118]
390.30	2.4	[118]
315.82	2.8	[118]
320.88	5.9	[118]

* Nitrous oxide – acetylene flame, in all other cases air – acetylene flames were used.
** Defined as the concentration in parts per million (μg/mL) in aqueous solution which produces a 1 % absorption signal (0.0044 absorbance) under optimum conditions.

In the first report of the use of atomic absorption for molybdenum analysis [121], stainless steel samples were employed with an air – acetylene flame and ammonium chloride as a releasing agent. If the composition in the molybdenum standard solutions is matched with that of the sample solution by addition of appropriate quantities of the other metal salts present in the samples [122], a releasing agent is not necessary. An alternative is to separate the molybdenum from other metals in the sample solution by liquid – liquid (or solvent) extraction. This technique can also be used to concentrate the molybdenum solution before analyzing it. For example, quantities as low as 10^{-4} % have been determined in silicate rocks by extracting molybdenum from the aqueous sample with 8-hydroxyquinoline [123]; toluene-3,4-dithiol and ammonium pyrrolidine dithiocarbamate can also be used as extraction agents. Rock samples can be fused with sodium hydroxide and baked at ca. 650 °C for 30 min; after cooling the residue is treated with sulfuric acid and filtered. Alternatively, the sample can be treated directly with acid and filtered. Molybdenum in the filtrate has been extracted with α-benzoinoxime into chloroform [124].

Volumetric Methods. In the volumetric procedure, molybdenum in solution is reduced by zinc in a Jones reductor, the emerging solution is led under the surface of a ferric sulfate solution and titrated with potassium permanganate [117].

Gravimetric Methods. The older of the two main gravimetric methods is the precipitation of lead molybdate by slow addition of a lead acetate solution to a hot dilute acetic acid – ammonium acetate buffer solution containing the molybdenum. Free mineral acids prevent complete precipitation of the molybdenum. Cobalt, copper, magnesium, manganese, mercury, nickel and zinc do not interfere. Sulfate must be absent if alkaline-earth metals are present. If chloride is present, addition of a large excess of the lead acetate solution must be avoided. Since many metals interfere with the determination (antimony, arsenic, chromium, iron, phosphorus, silicon, tin, titanium, tungsten, and vanadium), it is not suitable for the determination of molybdenum in steels.

The other important gravimetric method is fairly satisfactory for steels and involves precipitation of molybdenum with α-benzoinoxime and ignition of the precipitated complex to molybdenum trioxide, which is weighed.

The sample is dissolved in dilute (1 : 6) sulfuric acid and the solution is treated with a minimum amount (ca. 2 mL) of concentrated nitric acid to decompose carbides and oxidize the iron and molybdenum. The solution is boiled to expel nitrogen oxides and filtered if necessary. To the cool solution sufficient iron(II) ammonium sulfate solution is added to reduce vanadium(V) and chromium(VI) acids. An excess of a 2 % solution of α-benzoinoxime in ethanol is added at 5 °C, followed by bromine water until the solution is pale yellow, and then more α-benzoinoxime. The precipitate on the filter paper is washed with a freshly prepared solution containing 10 mL of the 2 % reagent solution and 2 mL of concentrated sulfuric acid diluted to 200 mL. After charring, ignition at 500 – 525 °C, and weighing, the residue is treated with 5 mL of concentrated ammonia to remove the molybdenum and tungsten trioxides and the residual solid is ignited and weighed. If tungsten is present the ammoniacal extract is acidified with sulfuric acid and evaporated to dense white fumes. After diluting, the tungsten is precipitated using cinchonine and weighed as the trioxide after ignition at 750 – 850 °C.

Another gravimetric method often described involves precipitation of molybdenum as sulfide and ignition to oxide. This is not satisfac-

tory because loss due to volatilization is likely to occur. The complex of molybdenum with 8-hydroxyquinoline, $MoO_2(C_9H_6ON)_2$, is precipitated within the pH range 3.3 – 7.6. It differs from complexes of the reagent with other metals in being insoluble in organic solvents and in many concentrated inorganic acids. The freshly precipitated compound dissolves only in concentrated sulfuric acid and in hot solutions of alkali-metal hydroxides. This determination allows complete separation of molybdenum and rhenium.

Colorimetric Methods. Molybdenum(VI) in acidic solution can be reduced to give mainly molybdenum(V), which forms a red complex with thiocyanate. This complex can be extracted from water with organic solvents, particularly oxygenated compounds, providing a very sensitive spectrophotometric method. Tin(II) chloride is a suitable reducing agent, preferably used in the presence of a little iron(II). The method can be used to determine molybdenum in steels.

The steel sample is dissolved in mixed hydrochloric – perchloric acids, heated until dense white fumes are evolved and finally heated for a further 6 – 7 min. After cooling the solution is diluted with water and made up to a known volume. An aliquot is reduced with tin(II) chloride in the presence of iron(II) and potassium thiocyanate is added. The color depends on the acid concentration (optimum value 1 mol/L) and the thiocyanate concentration (should not be less than 1 %). The red complex is extracted into 3-methyl-1-butanol and the optical density measured at 465 nm. When the quantity of Mo in a 1-cm cell is 10 µg the following elements cause an error greater than 3 % when present in the amount specified: vanadium > 0.4 mg (interference is prevented by washing the organic extract with tin(II) chloride solution); chromium(VI) > 2 mg; tungsten(VI) > 0.15 mg; cobalt > 12 mg; copper > 5 mg; lead > 10 mg; titanium(III) in the presence of fluoride > 30 mg. The method is also recommended for the determination of molybdenum present as a trace element in fertilizers and animal feeds, the complex being extracted from the aqueous solution using a 1 : 1 mixture of carbon tetrachloride and 3-methyl-1-butanol [125]. The sample solution is prepared by dry ashing the feed at $\leq 450\,^{\circ}C$, treating the ash with hydrochloric acid, and evaporating to dryness. The residue is successively extracted with hot hydrochloric acid, the penultimate treatment being to take to dryness with a little nitric acid. The combined extracts are diluted to give an approximately 1 mol/L solution of acid. Inorganic fertilizers are extracted directly with hydrochloric acid. After evaporation to dryness the residue is treated in the same way as the ash from feeds.

10. Economic Aspects

Three factors form the basic economic character of the molybdenum industry:

1) Molybdenum consumption
2) Molybdenum supply
3) Excess production capacity

The iron and steel industry accounts for ca. 80 % of all *molybdenum consumption* in the Western world. The balance of consumption is split between nonferrous metallurgical uses and chemical applications. Estimated consumption of molybdenum in the Western world in 1989 according to end use is as follows (exports to Eastern-Bloc countries are not included):

Alloy steel	35 %
Stainless steel	27 %
Mo-base and superalloys	12 %
Chemicals	11 %
Tool steel	9 %
Cast irons	6 %

The metallurgical uses of molybdenum are primarily for the fabrication of plant and equipment; its consumption follows the capital goods cycle. The chemical uses for molybdenum involve chiefly catalyst, lubricant, aqueous corrosion inhibition, and color applications whose demand adheres to general industrial activity.

Sources of *molybdenum supply* in the Western world in 1989 were estimated to be as follows:

Primary mines	41 %
By- and coproducts of copper mining	54 %
Imports from China	3 %
Recovery from spent petroleum catalysts	2 %

In general, the cash cost of nonprimary production is significantly lower than the cost of primary mine production. This cost advantage

enables nonprimary producers to sell at lower prices than their primary counterparts. Primary production is the first supply segment to react to changes in market conditions.

The molybdenum industry has significant *excess capacity*. Encouraged by unrealistic demand expectations, nearly 50 000 t of primary mine capacity was installed during the late 1970s and early 1980s. This, in combination with the continued growth of byproduct production and the emergence of China as a supplier, has resulted in a Western world supply capacity of over 125 000 t. Western world demand in 1989, including exports to the Eastern-Bloc countries, though at record levels, was only 95 700 t.

Tables 11 and 12 contain estimates for molybdenum supply and demand which show that production exceeded demand during most of the past decade. Tables 13 and 14 list the major molybdenum mines and conversion operations (molybdenum roasting and ferromolybdenum conversion).

11. Environmental Aspects

General Considerations. The regulation of chemical discharges into the environment is increasing dramatically and will continue to do so in the 1990s. Existing restrictions on molybdenum discharges will likely be enforced at the state or local level in the United States and at the national level in Europe.

General aspects of molybdenum in the environment are reviewed in [126]. Additional studies and reviews further explore the impact of molybdenum in the environment [127], [128]. Although molybdenum can cause problems in the environment when discharged in excessive quantities, the problems are well defined and are easily corrected in most instances.

Wastewater. Soluble molybdenum compounds exhibit medium to low levels of toxicity when discharged into either fresh water, salt water, or sewage treatment facilities. Table 15 summarizes relevant ecotoxicity data.

In the United States, effluent guidelines for molybdenum have been established for some industrial categories. These guidelines are technology-based and not toxicity-related. Calculation of individual discharge limitations is based on process production rates. The EPA has not established generic molybdenum limits for industrial discharges nor has it established

stream or drinking water standards for molybdenum.

Exhaust Gas. Molybdenum compounds are not specifically regulated as a component of process exhaust gases. Control of molybdenum compounds in exhaust gases is accomplished by use of standard equipment such as bag houses, cyclones, and scrubbers. Efficiency of removal is typically monitored by noting total suspended particulate discharge rates. Work place exposure

for insoluble molybdenum compounds in the United States is limited to 10 mg/m^3 [138] which is the same as the TLV – TWA for nuisance dusts. Soluble molybdenum compounds in the work place are controlled at 5 mg/m^3 [138]. Exposure limits in other countries may differ slightly from the U.S. values and should be consulted accordingly. Under the United States Emergency Planning and Community Right-To-Know Act, molybdenum trioxide is considered a toxic chemical and is subject to annual chemical release reporting [139].

Solid Waste. Within the European Economic Community (EEC) and some other European countries (e.g., Switzerland), the molybdenum content of sewage sludge used for agricultural purposes is subject to regulation. In the United States, the EPA is developing guidelines for use of sewage sludge in agriculture, and will set acceptable limits for metals. Industrial waste in the United States and the EEC is not specifically regulated as to molybdenum content.

The Netherlands has adopted soil and groundwater contamination guidelines for molybdenum [140]. The pollutants regulated are classified in the "Black" and "Grey" lists, and are derived from a 1976 EEC Directive [141]. Chemicals on the Black list are considered very toxic and are persistent and/or bioaccumulate. Chemicals on the Grey list, which includes molybdenum, are of general concern in the environment.

The most widely studied environmental problem with molybdenum is its impact on ruminants that graze on forage with a high molybdenum content [142]. Environmental protection must therefore first identify the probable land use and then develop the control strategy necessary to mitigate the impact. For example, treatment of soil with sewage sludge has to be controlled so that the soil molybdenum content does not exceed 10 mg/kg [143]. Liming of soil lowers the accumulation of molybdenum in the surface plow layer because of the increased solubility at alkaline pH [143]. Due to the biological antagonism of copper toward molybdenum, dietary supplementation of ruminants with copper mitigates the effects of molybdenosis [143]. Sewage sludge with a high molybdenum content usually has a high copper content too which reduces the probability of molybdenosis in ruminants foraging on sludge-treated pasture. Sludge with less than 50 mg/kg molybdenum on a dry weight basis should therefore be acceptable for long-term land application at an annual addition rate of 10 000 kg/ha.

12. Toxicology and Occupational Health

" Molybdenum compounds in general are of a low order of toxicity, both from the point of view of observed clinical effects as well as from the histopathologic point of view" [144]. Toxicity is primarily associated with soluble molybdenum compounds. For example, both inhalation and ingestion of insoluble molybdenum disulfide and calcium molybdate failed to produce significant histopathological findings in either rat or guinea pigs [144].

Human Nutrition. Molybdenum is an essential trace element. Leguminous plants require molybdenum for bacterial fixation of nitrogen. In animals and humans it serves as a cofactor for the enzymes xanthine oxidase (which oxidizes xanthine to uric acid[145]) and aldehyde oxidase. Probably 25 – 75 % of molybdenum in the diet is absorbed through the gastrointestinal tract and is rapidly eliminated, primarily via the urine. The biological half-life is not well established for humans, but most of the absorbed molybdenum is eliminated within a few days or weeks. Animal data indicate that the metabolism of molybdenum is closely related to the metabolism of copper and sulfur compounds [146].

The normal daily human dietary intake of molybdenum in the United States is estimated to be 100 – 500 µg. High molybdenum concentrations are generally found in leafy vegetables (up to 5 µg/g wet weight); legumes with edible roots have a low molybdenum content (< 1 µg/g wet weight). There are no human or animal studies implying accumulation of molybdenum in the body during the life cycle [147].

The relationship of molybdenum deficiency and esophageal cancer in humans was first reported in 1966 [148]. The high incidence of this cancer was attributed to the consumption of food locally grown in soil low in molybdenum. As reported in 1981, a study in China demonstrated an

inverse relationship between the mortality rate of esophageal cancer and the content of Mo, Zn, Mn, Si, Ni, Fe, Bi, and I in cereal and drinking water samples [149]. Levels of molybdenum in the serum, hair, and urine of the inhabitants of the high-risk area were lower than those in the low-risk areas. Utilizing animal models, this inhibitory effect of molybdenum on esophageal, fore stomach, and mammary carcinogenosis has been demonstrated in laboratory studies [150], [151], [152].

Human Toxicity. Information on the toxic effects of molybdenum in humans is scarce. A 1961 study reported a high incidence of gout in an area of Armenia in which the soil contained 77 mg/kg of molybdenum and 39 mg/kg of copper [147]. Daily dietary intake of molybdenum was calculated to be 10 – 15 mg and that of copper 5 – 10 mg; corresponding values in the control area were 1 – 2 mg Mo and 10 – 15 mg Cu. The study showed an increased prevalence of goutlike joint disorders, elevated blood levels of uric acid, and an increase in the urinary excretion of uric acid [147]. The results are difficult to evaluate since no details are given concerning the study population and the selection of subjects. Furthermore the control group consisted of only five subjects.

A study in another high-molybdenum province in the formerSoviet Union failed to detect biological changes in the study population. A tentative explanation is that a higher intake of natural copper may have protected the population against the molybdenum exposure [147]. Animal studies have demonstrated a biological antagonism of copper toward molybdenum.

A study of four humans in India, detected a significant increase in copper metabolism with dietary intakes of molybdenum ranging from 160 to 2540 µg/d. However, the study failed to detect any effect on the urinary excretion of uric acid [153].

On the basis of the above studies, MERTZ suggests that a dietary intake of more than 10 mg/d of molybdenum is dangerous to human health, but that intakes of up to 1.5 mg/d do not appear to have an effect except for an increase in urinary copper excretion [154]. With a daily molybdenum intake of 540 µg, copper excretion was elevated but was still within normal range. In adult humans with a normal copper intake (1.5 – 2.5 mg/d), MERTZ proposes that a dietary molybdenum intake of 0.5 – 1.0 mg/d can be assumed to be safe. Based on balance studies conducted in areas where the diet is generally adequate in molybdenum and no molybdenum disease has been observed in humans, the U.S. National Academy of Sciences has estimated an adequate and safe intake of molybdenum for humans as being 0.15 – 0.5 mg/d [155].

Animal Toxicity. Most observations on the toxicity of molybdenum are based on animal data. Excessive exposure to molybdenum via food can cause severe disease in ruminants which involves diarrhea, anemia, and emaciation, and may progress to death. The disease was first identified in 1938 as the cause of a long-recognized problem in cattle grazing in areas called "teart" pastures in Somerset, England. By 1943 large doses of copper sulfate were shown to prevent or cure "teart" disease. The clinical signs of molybdenum toxicity in animals are primarily due to copper deficiency. After long exposure, the hair loses its color and lameness with a characteristic stiff gait may develop. The latter symptoms may be associated with disturbance of phosphorous metabolism resulting in osteoporosis and joint abnormalities [156].

Young lambs grazing on high-molybdenum pastures suffer from a bone or joint disorder known as swayback. Sheep also develop steely wool, but not the severe diarrhea seen in cattle [157]. Copper deficiency in lambs also lowers their resistance to infections, such as pneumonia [158].

Evidence indicates that cattle are the most susceptible to molybdenum toxicity of any species, followed by sheep. Horses grazed the "teart" pastures of Somerset without showing any clinical signs of toxicity. Rabbits [159], guinea pigs, rats, pigs, and chickens [158] are comparatively tolerant to molybdenum.

Due to the great variability in results, the data available for cattle and sheep provide little assurance about safe levels of molybdenum; a level of 5 – 10 ppm in pasture forage is usually considered a conservatively safe molybdenum level. The clinical symptoms of molybdenum toxicity or molybdenosis are primarily due to a conditioned or secondary copper deficiency. The most reliable indication of molybdenosis or copper deficiency is alteration of the symptoms by cop-

per supplementation. In some areas where animal forage is deficient in copper, pastures with molybdenum levels normally considered to be in the safe range could trigger signs of molybdenosis. At the other extreme, forage that is naturally high in copper produces copper toxicity and supplemental dietary molybdenum may be necessary.

The results of acute toxicity tests (LD_{50} and LC_{50} values) are given in Table 15. In literature citing acute testing, low LD_{50} values (i.e., high toxicity) are sometimes given for molybdenum compounds. Some of these low levels are the result of long-term feeding studies but are interpreted as single-dose acute studies. For example, the acute oral LD_{50} in rats for molybdenum trioxide is frequently listed in the literature as 125 mg/kg, indicating that it is highly toxic. This LD_{50} was, however, determined by a 44-day feeding study [144], not by a single dose. The acute oral LD_{50} of molybdenum trioxide, pure grade, when determined by a single dose in rats, ranges from 2960 mg/kg to 3520 mg/kg [160].

Occupational Health. Several studies on the industrial exposure of humans to molybdenum have been reported from the former Soviet Union. A 1963 study reported 3 cases of pneumoconiosis out of 19 workers exposed to metallic molybdenum and its oxide. Early signs of pneumoconiosis were identified by X-ray in a 44-year old woman exposed for 5 years to molybdenum concentrations ranging from 1 – 3 mg/m^3 and in a 44-year old man exposed for 4 years to concentrations between 6 and 19 mg/m^3. A 34-year old man exposed for 7 years to concentrations between 6 and 19 mg/m^3 showed fully developed pneumoconiosis [161].

In another former Soviet study 73 workers in a copper – molybdenum plant complex and 10 control subjects were studied [162]. Workers with the highest exposure had the highest blood level of uric acid, and increased blood uric acid was found in 34 out of the 37 workers who complained of arthralgia. The actual values of uric acid in blood were not reported in this study, nor was the exposure defined.

Hyperuricemia was also described in another study on 85 workers in a copper – molybdenum plant in Kadzaran, former Soviet Union [163]. An increase in blood concentrations of bilirubin, globulins, and cholesterol was observed but no values or exposure data were provided. In a study on 500 workers from a former Soviet molybdenum and copper mine, nonspecific symptoms and changes in the central nervous system were reported. Molybdenum dust levels in the mines were in some cases 10 – 100 times higher than the Soviet maximum permissible level of 6 mg Mo/m^3 [164].

The effects of molybdenum exposure was studied in 25 male workers [mean age 28.3 years (19 – 44 years), mean duration of employment 4.0 years (0.5 – 20 years)] from a roasting plant in Denver, Colorado, where molybdenum sulfide was converted to molybdenum oxides [165]. Total dust samples were collected in the roaster area and the 8-h time weighted average (TWA) molybdenum exposure was calculated to be 9.47 mg/m^3. The respirable ($< 10\,\mu$m) molybdenum concentration in the dust at the base of the roaster was 1.02 mg/m^3 and the minimum daily body burden of molybdenum was calculated to be 10.2 mg. Urinary and plasma molybdenum levels were higher for the worker group than for the control group. Except for some generalized medical complaints, the only adverse biochemical findings were elevated serum ceruloplasmin levels and a small increase in serum uric acid the mean value of which was within the normal range of the control group. No gout-like symptoms were reported. Urinary copper excretion was normal in 13 of the 14 workers.

In the United States, health and safety regulations have established permissible exposure limits (PELs) in the occupational environment at 5 mg/m^3 for soluble molybdenum compounds. The Threshold Limit Values (TLVs) have also been established by the ACGIH for soluble and insoluble molybdenum at 5 and 10 mg/m^3, respectively. Both the PELs and TLVs are time-weighted averages (TWAs) for 8 h/d. Although the study of the 25 workers [165] may be considered limited because of the small population and high employment turnover, the absence of any adverse health effects at an exposure level approximately twice the soluble molybdenum PEL is of considerable value in assessing the potential worker risk to molybdenum exposure.

1. Introduction

Antibodies are proteins produced in the blood of all vertebrate species and are one of the mechanisms for defending the organism against invasion by bacteria, viruses, or other foreign material. Each animal can produce millions of different antibodies, each antibody being able to bind specifically to a particular foreign substance known as an *antigen*.

Figure 1. Schematic representation of an immunoglobulin (Ig) molecule (reproduced with permission [2])
The tertiary structure of Ig molecules is composed of interacting protein domains. The heavy chain domains (C_H2 and C_H3) interact with like domains; the light chain domains (C_L and V_L) interact with heavy chain domains (C_H1 and V_H). Inter- and intrachain disulfide bridges (–S–S–) stabilize the structure.

All antibodies have a similar structure based on a unit of four polypeptide chains (Fig. 1): two identical *heavy chains* (M_r ca. 50 000) and two identical *light chains* (M_r 25 000) [1]. The protein fraction containing antibodies (the immunoglobulin or Ig fraction) can be purified from blood by simple physicochemical procedures (e.g., salt precipitation, →Immunotherapy and Vaccines, Chap. 5.1.). This fraction contains a very large number of antibody molecules that are structurally similar but differ in their antigen-binding specificity. Further purification of a single antibody must, therefore, rely on specific antigen-binding properties. Purification methods based on this principle have been extensively used but the heterogeneity of the normal immune response to even a single, simple antigen has limited their usefulness.

In the 1960s it was shown that antibodies are made by *lymphocytes* (a type of white blood cell) and that each lymphocyte makes only a single antibody. Maintenance of clones derived from single lymphocytes in long-term culture, could therefore provide a source of single, pure antibodies. Occasionally, this happens naturally in a form of cancer (*myeloma*) that results from the uncontrolled proliferation of a clone of cells derived from a single lymphocyte. Pure antibody in large quantities can be derived from the blood of tumor-bearing animals but the rarity of the disease and the apparent randomness of the transformation event make it impossible to identify the specificity of the antibody.

In 1975 Georges Köhler and César Milstein discovered a general method for the immortalization of lymphocytes making antibodies of predefined specificity [3].

10.1002/14356007.a16_699

They injected a mouse with a single antigen to boost the number of lymphocytes making specific antibodies. Lymphocytes removed from the mouse were then fused with cells derived from a previously isolated mouse myeloma. The resulting hybrid cell (*hybridoma*) was able to grow permanently like the parent myeloma and secreted the same specific antibody as the parent lymphocyte. Hybridomas derived from a single lymphocyte are monoclonal and the antibodies they produce are called *monoclonal antibodies*.

Since its introduction, monoclonal antibody technology has had a dramatic impact on life science research and clinical medicine. The extensive introduction of immunological methods based on monoclonal antibodies amounts to a revolution, the importance of which was recognized by the award of the Nobel Prize for medicine in 1984 to Köhler and Milstein.

Although other methods of lymphocyte immortalization have been used to produce monoclonal antibodies, the original method of Köhler and Milstein (Chap. 2) remains the basis for the majority of monoclonal antibody derivation today. It has been very successfully used to produce mouse and rat hybridomas, but the derivation of human monoclonal antibodies has proven particularly difficult (Chap. 3). The derivation of hamster hybridomas is becoming a well-established method using mouse myelomas as fusion partners to derive hamster – mouse *heterohybridomas* [4]. The production of heterohybridomas of either rabbit [5] or cow origin have been reported [6] but not developed into general methods. With the rapid progress of genetic engineering techniques, direct antibody gene cloning may become the method of choice for the future derivation of monoclonal antibodies (Chap. 3).

2. Derivation of Murine Monoclonal Antibodies by Somatic Cell Fusion

Somatic cell fusion is the process by which two somatic (body) cells are fused together to give a viable hybrid cell that carries some of the genotypic and phenotypic characteristics of the two parent cells. For the derivation of hybridomas, poly(ethylene glycol) (PEG) is used to fuse a large number of spleen cells from an immunized donor with cells of a suitable myeloma line.

Spleen cells from immunized animals can produce specific antibodies, but die after a short time in culture. Myeloma cells have been adapted to grow permanently in culture, and mutants have been isolated that lack either the enzyme hypoxanthine guanine ribosyltransferase (azaguanine-resistant) or thymidine kinase (bromodeoxyuridine-resistant). Unlike normal cells, they are unable to utilize hypoxanthine or thymidine for DNA replication. Such mutants therefore cannot grow in media containing aminopterin and supplemented with hypoxanthine and thymidine (HAT-selective media); aminopterin blocks the utilization of essential amino acids for the synthesis of these purine and pyrimidine bases. Hybrids between these mutant cells and spleen cells can therefore be selected from the parents because they are the only cells that actively multiply in HAT-selective media.

From the growing hybrids, individual clones can be selected that secrete the desired antibodies. Such antibodies are thus of monoclonal origin. The selected clones, like ordinary myeloma lines, can be maintained indefinitely.

A scheme for the general procedures involved in the derivation of monoclonal antibodies is illustrated in Figure 2. Overall the process takes between three months and one year depending on the antigen and on the monoclonal antibody characteristics required. A number of well-defined steps can be identified:

1) The animal is immunized with the antigen of choice
2) The myeloma cells are prepared in sufficient quantities and proper growth phase (spinner culture)
3) Spleen cells and myeloma cells are fused and hybrids selected by the use of HAT medium
4) Antibodies of particular interest are isolated and established in culture by repeated cycles of cloning and screening
5) Frozen stocks of hybridomas are prepared throughout the procedure so that if individual cultures are intentionally or accidentally stopped it is possible to go back to earlier stocks
6) Selected clones are propagated in vitro or in vivo for large-scale production of monoclonal antibody and for the preparation of consistent banks of vials that can be kept below −80 °C for several years

Figure 2. The process used for the derivation of monoclonal antibodies (reproduced with permission from [7])

Although this basic scheme has remained unchanged since 1976, a large number of variations have been introduced; for efficient derivation of specific monoclonal antibody the procedure must be carefully planned and prepared.

Cells and Fusion. The vast majority of monoclonal antibodies are made from immunized mice, but rats are also used. The choice of animal strains and the immunization procedure depend on the antigen to be used and on the requirements for the monoclonal antibody product.

A number of mouse and rat myeloma cell lines have been developed specifically for hybridoma derivation (Table 1). They differ in their specific drug resistance and their ability to secrete myeloma proteins. Since myelomas originate from lymphocytes, they generally secrete immunoglobulins of undefined specificity (hence the term myeloma proteins rather than antibody). Hybridomas derived from them secrete both the antibodies derived from immunized spleen cells and the myeloma protein. The two sets of immunoglobulin are difficult to separate, and it is generally a considerable advantage to use mutant myelomas that no longer make myeloma proteins but are still able to secrete antibody when fused with spleen cells. A number of protocols have been developed for cell fusion [10]. Most are based on mixing spleen cells and myeloma cells and treating the mixture for a few minutes with poly(ethylene glycol) solutions. An important alternative to the use of a chemical fusing agent is the use of a strong electric field [18].

Screening. Fusion results in a viable mixture of residual nonfused spleen cells and a few hybridomas (generally 1 for every 10 000 spleen cells). This mixture is aliquoted in a number of cultures and incubated with selective media. In 5 – 20 days, the only remaining cells in the cultures will be hybridomas. Intensive screening is then necessary to identify the cultures that contain a hybridoma secreting the antibody of interest. Screening consists of harvesting spent culture media and subjecting these to immuno-

logical tests to detect the presence of specific antibody.

The choice of assay used for the screening stage is extremely important. Different screening assays detect antibodies with different characteristics, e.g., different antigen specifity, cross-reactivity with molecules similar to the specific antigen, different binding affinity, and different antibody effector functions. Immunologists have developed an enormous variety of methods for detecting the presence of antibodies ranging from precipitation reactions and radioimmunoassays to assays based on the biological activity of the recognized antigen [19]. These methods can very often be adapted.

Binding assays are probably most generally used on account of their specificity, accuracy, and versatility. Insoluble antigens (either naturally insoluble or absorbed on an appropriate solid support) are allowed to react with the antibody in the culture fluid. The free antibody is washed away. The amount of monoclonal antibody bound is measured directly (direct binding assay) or by binding a second, labeled antibody capable of recognizing the first (indirect binding assay). This second antibody can be labeled in several ways: radioactively labeled, fluoresceinated, and enzyme-linked derivatives are the most common.

Although less extensively used, *assays based on the biological activity* of the antigen are of particular importance because they allow the detection of antibody to antigens that are only identified by their biological activity but cannot be chemically purified. The first example of this was the production of monoclonal antibody to human interferon [19]. A biologically active antigen preparation can be added to the culture supernatants to be screened. After incubation a decrease in biological activity is assumed to be preliminary evidence for the presence of inhibitory antibody. Alternatively, the precipitation of antibody – antigen complexes can be effected (for instance by addition of anti-mouse or anti-rat immunoglobulin) thus removing part of the biological activity from the supernatant.

Cloning. Once cultures of hybridomas secreting specific antibody are identified, they can be cloned (i.e., individual cells physically separated and propagated in individual cultures). The best way is to culture the cells embedded in a semisolid agar-containing medium [10], [20]. Clones are generally rescreened, often using a battery of screening assays to select clones meeting more stringent criteria of antibody production and specificity.

Probably the most important feature of hybridoma technology is that immortalization by cell fusion and cell cloning allow the preparation of antibody specific for an individual antigenic determinant present in a mixture, without the need for purifying the antigen.

Figure 3. Antibody (Ab) production by animals and by hybridomas (reproduced with permission from [21])
Isolation of hybridoma clones allows the preparation of monospecific antibodies starting from a complex mixture of antigens.

When an animal is injected with an antigenic mixture, its usual response is the production of a highly heterogeneous population of antibody directed against the immunogen. Some of these antibodies are specific for various com-

ponents of the antigenic mixture and are mixed with many others that express other properties. When monoclonal antibodies are prepared, the collection of randomly derived clones represents a cross-section of such a heterogeneous population. The strength of the response to each individual antigenic determinant is reflected in the hybridoma population producing antibody to that determinant (Fig. 3).

Thus the derivation of monoclonal antibody to antigens present in a complex mixture has become a powerful tool for the definition and identification of previously unknown components of the mixture. The most spectacular example is the derivation of a very large number of monoclonal antibodies for mammalian cell surface antigens to define or "map" the structure of the cell surface [22].

3. Human Monoclonal Antibodies

For many potential medical applications of monoclonal antibodies the ultimate goal is a general method for the production of human monoclonal antibodies. Although several instances of human monoclonal antibody production have been reported, two main problems have been encountered in the development of a general methodology. The first is the problem of obtaining highly immunized human lymphocytes for use in the fusion. The second is the production of a monoclonal antibody in the absence of suitable myeloma partners.

A key feature of the standard technique for mouse monoclonal antibody production is the ability to repeatedly inject laboratory mice with the specific antigen. Although this is sometimes possible in humans (e.g., tetanus toxoid vaccination), it is clearly unethical to immunize humans with most antigens. The need for alternative sources of immunized human lymphocytes has led to the development of two new techniques that avoid the requirement of injection of the antigen into humans. The first consists of adding the antigen to a suspension of human blood lymphocytes in a culture medium that allows the necessary differentiation of the lymphocytes to antibody-producing cells [23]. Although not yet a routine operation, this in vitro immunization method has become more feasible with the availability of recombinant growth factors and lymphokines [23]. A more recent and promising advance is the discovery that human lymphocytes can be grown in a strain of mice suffering from Severe Combined Immune Deficiency disease (SCID mice). Human lymphocytes are used to repopulate the immune system of the mouse, and the animal responds to immunization by making human antibodies. Human cells growing in the spleen of such an animal have been fused with myeloma cells to produce a human monoclonal antibody [24].

This exciting development may open the door to the first routine method for the derivation of human monoclonal antibodies. A step beyond transfer of human lymphocytes to a mouse host would be the transfer of the genes coding for human antibodies. This may soon become reality with the development of transgenic mice [25].

However immunization is performed, a second major problem in the production of human monoclonal antibody is the absence of suitable myeloma partners. Mouse – human heterohybridomas are unstable and none of the available cell lines has become generally accepted. Despite considerable efforts, no reliable, consistent methodology based on somatic cell fusion alone has emerged. Alternative approaches to lymphocyte immortalization have therefore been explored.

Even before the advent of hybridoma technology the natural transformation of human lymphocytes by viruses had been used to derive stable cell lines. In most cases, however, these were unable to secrete useful amounts of antibody over a long period of time. The combination of viral transformation followed by somatic cell fusion has resulted in the most successful technique presently available for the derivation of human monoclonal antibodies [26].

Due to the above problems, the production of human monoclonal antibodies by hybridomas is likely to be based on genetic engineering. Antibodies of all species have relatively independent protein domains of about 110 amino acids folded in a characteristic shape (Fig. 1). Although the amino acid sequence is species-specific, the domain shape is common to all known antibodies and the domain carrying the antigen-binding specificity (V domains in Fig. 1) can be transplanted from the antibody of one species to another. Although this cannot be achieved directly on the protein, recombinant DNA technology

has allowed antibody genes to be cloned and antibody gene domains to be reshuffled. The engineered genes are then expressed in a suitable mammalian host cell line that can be grown like a hybridoma. An example of a "reshuffled" antibody is the "chimeric" antibody that consists of the antigen-binding domain of the mouse monoclonal antibody B 72.3 attached to the remaining domains from a human antibody. The original (mouse) B 72.3 recognizes an antigen present on human tumor cells; the chimeric antibody has identical binding properties to the mouse antibody and is now being tested in clinical trials as a potential therapy for colon cancer [27]. Chimerization of antibodies has become a subject of considerable industrial interest.

A recent refinement of this technology has been achieved by grafting onto a human antibody molecule only those parts of the antigen-binding domain that are actually in physical contact with the antigen [28]. Whether this will prove to be a practical improvement for chimeric antibodies remains an open question.

4. Production

Monoclonal antibodies accumulate in the spent media of growing hybridomas at an average concentration of 10 – 100 mg/L. The productivity is a characteristic of individual clones, but is strongly affected by culture conditions. Under optimal conditions productivity may reach 500 – 600 mg/L.

Small volumes of supernatant can be collected either from stationary cultures ("flasks" of up to 1 L) or from slowly rotating bottles ("rollers" of up to 3 L). These conditions are generally satisfactory only for laboratory-scale production (<1 g). For larger quantities two alternatives are available: the hybridomas are either grown as tumors in animals or in an industrial-scale cell-culture plant.

Whichever culture technique is used, a number of important considerations apply:

1) The system must be effectively sterilized before introduction of cells, and maintained free of microorganism contamination for prolonged periods (months for continuous cultures). Small vessels may be sterilized by autoclaving, but large production plant must be sterilized in situ, generally by steaming at high temperature and pressure. Materials and engineering standards have to be of high quality.
2) For effective cell growth and antibody production, the system must provide adequate mixing. Heat and mass transfer characteristics must be sufficient to maintain correct temperature, pH, dissolved gas and nutrient concentrations.
3) Maximum economy of scale cannot be achieved by simply increasing the number of production units.

Production in Animals. When hybridomas are grown in animals (either as solid tumor or as ascites), the monoclonal antibody accumulates in the blood or in the peritoneal cavity at very high concentration (5 – 20 mg/L) but the volume that can be harvested from each animal is rather small and therefore large numbers of animals are required (around 20 000 mice to produce 1 kg of antibody).

Production in Cell Cultures. In addition to the ethical considerations, production in cell cultures has other considerable advantages over production in animals:

1) Monoclonal antibody purified from blood is always contaminated with other antibodies of the same species and class, naturally produced by the animal, and these are difficult to eliminate.
2) The risk of contamination with rodent viruses is eliminated.
3) The process can be automated and made reproducible
4) Scaling up the process by increasing the number of animals does not provide the economy of scale offered by scaling up of industrial fermentation.

With product safety legislation becoming ever more stringent it may soon even be impossible to produce antibodies for therapeutic use in animals.

A wide variety of systems have been developed for in vitro production of monoclonal antibody and are treated in depth in [29]. The most relevant methods will only be summarized here. They depend on growth in free suspension (homogeneous suspension cultures) or

as immobilized cell cultures. More than 50 % of monoclonal antibody production is probably performed with homogeneous suspension cultures.

Homogeneous Suspension Culture. Two types of homogeneous suspension systems have been developed and are used extensively: continuously stirred deep-tank fermenters (originally developed for microorganisms) and airlift fermenters. Although not yet extensively used for monoclonal antibody, stirred deep-tank fermenters (up to 80 000-L capacity) have been used to grow lymphoblastoid cells for interferon production [30]. The airlift fermenter has an internal, concentric draught tube (Fig. 4). Gas mixture introduced from a sparge ring inside the base of the tube causes the culture medium to circulate. Control of gas pressure controls the circulation, and changes in gas mixture composition are used to adjust the pH and dissolved oxygen tension. Airlift fermenters of up to 2000-L capacity have been used for monoclonal antibody production [31].

Figure 4. Schematic diagram of an airlift fermenter

Suspension cultures are usually operated in a batch mode but may also be used for continuous culture in which a feed of fresh medium is added to the culture over a prolonged period and the culture is at the same time continuously harvested at an appropriate scale to maintain a steady state [32].

Immobilized Cell Cultures. Various systems have been developed in which the cells are immobilized on a solid matrix (microcarrier), in microbeads, in hollow-fiber reactors, or on ceramic or glass matrices.

The use of *microcarriers* was first developed for bulk cultivation of anchorage-dependent cells [33] but microcarriers with surface charge properties suitable for the absorption of suspension cells are now used. Suitable microcarrier materials include cross-linked dextran, collagen, gelatin, glass, plastic, cellulose, and even droplets of a liquid that is immiscible with the culture medium (perfluorinated hydrocarbons, [34]). Cells immobilized on microcarriers can be grown in either perfusion culture systems or in fluidized-bed reactors.

In *microbead culture*, cells are encapsulated in semipermeable microbeads of agarose or alginate. The technique of alginate encapsulation, pioneered by Lim and Son [35] has been developed for industrial-scale cultivation by Damon Corporation [36]. As with microcarriers, encapsulation of cells lends itself to perfusion culture. Cells can grow to very high population densities and crude products can be retained at high concentration within the capsules.

Monoclonal antibodies have also been produced using *hollow-fiber reactors* which consist of loose bundles of semipermeable capillary fibers enclosed within a culture chamber. Cells grow within the culture chamber in the extracapillary space while the culture medium is circulated through the capillary. Gases, nutrients, and catabolites of low molecular mass diffuse between the culture chamber and the inside of the fibers along their respective concentration gradients; macromolecular products including the monoclonal antibodies are retained within the culture chamber from where they can be harvested at relatively high concentration [37].

The hollow-fiber principle is also used in the flat-bed membrane bioreactor [38] which contains three chambers: a culture chamber bounded on one side by a perfusion chamber and on the other by a harvest chamber. A semipermeable membrane separates the central culture chamber from the perfusion chamber through which a feeding medium is circulated. The other side of the culture chamber is separated from the harvest chamber by a microporous membrane, which allows the passage of macromolecules but not cells. Macromolecules, including the desired antibody product can thus be recovered from the harvest chamber.

Ceramic or glass matrices have also been developed for the immobilization of hybrido-

mas [39]. They are used in reactors in which the culture chamber is filled with porous rigid honeycomb units or beads.

5. Purification

Antibody can be recovered from cell cultures or from ascitic fluid by a wide variety of methods depending on the purity required. For preparation of diagnostic reagents, ascitic fluids or concentrated spent culture media can often be used directly, although some simple purification is generally used. High-purity material is, however, necessary when the monoclonal antibody is to be injected into patients for diagnostic (e.g., tumor imaging) or therapeutic purposes. Levels of contaminants such as proteins, nucleic acids, and pyrogens must also be reduced to acceptable levels. Furthermore the purification process must be validated to confirm that it removes contaminating substances irrespective of whether their presence can be demonstrated in the antibody source.

To achieve high purity, control of the environment in which the purification process is run is essential. Equipment used exclusively for monoclonal antibody production must be installed in a purpose-built facility.

Figure 5. Flow sheet of monoclonal antibody production

The most important purification methods will only be summarized, more details can be found in specialized references [40]. A typical flow sheet is shown in Figure 5. In most cases the first step in antibody purification is some form of *clarification* to eliminate macroimpurities (lipids in ascites and cell debris from culture supernatants). This is generally achieved by either filtration and/or centrifugation (see also → 11. Biochemical Separations, Chap. 4.1.→ 11. Biochemical Separations, Chap. 4.2.). Culture supernatants are then usually concentrated by ultrafiltration, or (for smaller scale production) by protein precipitation.

Nearly all published antibody purification processes employ a chromatographic step. A more detailed description of industrial-scale chromatography is given elsewhere (→ Process-Scale Chromatography). One of the most common methods is *ion-exchange chromatography* because cellulose-based ion exchangers are economical and their use in protein purification is well documented. Each monoclonal antibody has an isoelectric point in the pH range 4.7 – 8.3 and this dictates the operating conditions and the particular matrix for optimal purification.

Since most serum proteins are acidic, ion exchange is particularly favorable for separating the basic antibodies. Ion exchange has been used both as a single purification step to achieve relatively pure antibodies used for diagnostic or immunopurification purposes, and as a final step to clean affinity-purified antibody for therapeutic purposes.

Purification of monoclonal antibody by *affinity chromatography* using, for example, Protein A Sepharose (Pharmacia) is another very popular method. This offers the advantages of giving a high degree of purity and high yield in a single step, even from very dilute supernatants. Not all antibody subclasses and species bind equally well to protein A. However, since the interaction of antibody with protein A is primarily hydrophobic, the introduction of a buffer with a high salt concentration enhances binding considerably and effective purification processes for most monoclonal antibodies can be designed [41]. Affinity chromatography is best used as the first chromatographic purification step due to its very high purification power. Although the matrix is very expensive, the columns can be used

for over 100 cycles. Large quantities of monoclonal antibody are commonly purified by using several purification cycles for each batch. Thus, with a 500-mL protein A column of 4 g capacity, up to 400 g of antibody can be purified in 100 cycles. Automation reduces costs and allows fine tuning of the purification process.

Affinity chromatography matrices are not easy to sterilize. Although Protein A Sepharose columns can be sterilized with a variety of agents (e.g., guanidine hydrochloride, hibitane and benzyl alcohol, propylene oxides) the purification process is usually designed to minimize the need for repeated sterilization. All solutions are sterilized before they come into contact with the column.

Although very high purity may be obtained in a single step by affinity chromatography, antibody for therapeutic use generally requires further purification to reduce the levels of contaminants to acceptable limits. This is often achieved by ion-exchange chromatography to bind the impurities. Because of high concentration and relatively small volumes involved, better antibody yields are obtained than if ion exchange is used at the outset.

6. Monoclonal Antibody Patents

The opportunity to obtain patent protection relating to hybridoma – monoclonal antibody technology was missed when the original publication was allowed to proceed without a patent application being filed [3]. With the benefit of hindsight, it is likely that a generic technology patent position could have been established with patent terms extending into the mid-1990s.

Subsequently, attempts were made to establish broad monoclonal antibody patents directed to classes of antigens, e.g., the Koprowski – Wistar patent applications relating to monoclonal antibodies to viral antigens and tumor-associated antigen [42]. Patents were granted on these filings in the United States, although the corresponding patents were rejected by the United Kingdom Patent Office. Broad patent applications were also filed by Hybritech directed to the use of monoclonal antibodies in immunoassays [43]. Again, patents have been granted in the United States and have now been upheld by the United States Courts in patent infringement actions. The corresponding European Hybritech patent would, however, probably be held invalid if challenged. The difference reflects the United States "First to Invent" and European "First to File" patent law.

To obtain patent protection, it is necessary to have identified a new, nonobvious invention over the "State of the Art" at the initial filing date. Furthermore once monoclonal antibody technology had been established, its application to a particular known antigen is unlikely to give rise to a patentable invention. Thus, following the early broad patents of Koprowski and Hybritech, the scope for other broad monoclonal patents was somewhat limited. Early exceptions, however, were the patents relating to T-cell markers (i.e., Ortho OKT series patents [44]) where the application of hybridoma – monoclonal antibody technology resulted in the identification and dissection of a new class of antigen, and the Secher and Burke patent where special problems had been encountered in obtaining monoclonal antibody to interferon [45].

Following on from these precedents, monoclonal patent opportunities are likely to arise in three main circumstances:

1) The identification of subsets of monoclonal antibodies with special benefits over other monoclonal antibodies for the antigen in question; for instance, as the result of identification of a critical antigenic epitope.
2) The identification of an individual hybridoma cell line. Although specific cell lines have been successfully patented in this way, it is generally thought that the protection afforded by such a patent can be more effectively achieved by controlling the distribution of the cell line.
3) The development of new, useful technologies for preparation of monoclonal antibodies. An exciting opportunity would be a satisfactory solution to the problem of deriving human monoclonal antibodies.

7. Uses

Explosive growth in the annual number of new scientific publications relating to monoclonal

antibodies (Fig. 6) reflects the enormous diversity of the uses of monoclonal antibodies. Extensive reviews can be found in [40], [46].

Figure 6. Number of scientific publications relating to monoclonal antibodies from 1975 to 1988 (Medline scientific references data bank)

In this short section a few general statements will be made, followed by a highly selected but illustrative list of applications.

Research Applications. The opportunity that monoclonal antibodies offers to dissect complex antigenic mixtures (Chap. 2) is the key to the dramatic impact that the technology has had on biological research. Immunology, neurobiology, and embryology for example have all witnessed great leaps forward in the past decade as a result of the application of hybridoma technology to describe the complex structure of cell surfaces. Disciplines less familiar with immunology (e.g., botany and chemistry) were slower to realize the full potential of monoclonal antibodies, but are now catching up rapidly.

In immunoassays, such as that used to measure thyroid hormones, monoclonal antibodies have almost completely replaced conventional antisera. Furthermore, because of their availability in large quantities and defined specificity and affinity, monoclonal antibodies have allowed the extension of immunoassay techniques into areas that were previously impractical. For example, assays using labeled antibodies (immunometric assay) are overtaking assays in which the antigen is labeled (radioimmunoassay).

The use of antibodies immobilized onto chromatographic matrices for immunopurification had previously been described using polyclonal antibodies but only with monoclonal antibodies has this technique become of general practical use, e.g., for the purification of interferon [19]. The exquisite specificity of monoclonal antibodies has also had an impact on the reliability and quality of immunohistochemistry.

Monoclonal antibodies are now also used as pharmacological tools to neutralize biologically active molecules or to interfere with specific ligand – receptor interactions.

Clinical Practice. The first important clinical use of monoclonal antibody was for the typing of human blood.

Diagnostics (→Diagnostic Reagents, Chap. 3.→Diagnostic Reagents, Chap. 4. Process-Scale Chromatography,). Monoclonal antibodies have allowed the development and commercial introduction of prepacked "kits" for the measurement of a variety of clinically relevant molecules. The introduction of diagnostic methods relying on enzyme rather than radioisotope labels has led to a rapid expansion of immunoassays in clinical practice.

Within clinical laboratories, the tendency towards full automation has been greatly accelerated by the introduction of monoclonal antibodies. Of equal or even greater importance is the development of simple kits that can be used in the doctor's office or even at home. The best example of this trend is the phenomenal growth in the market for home-based pregnancy detection and fertility testing. Another growth area is the development of tests for infectious disease agents. Here the specificity of monoclonal antibodies has been of paramount importance in developing tests of high diagnostic efficiency.

Rapid growth has also been seen in oncology, where tests for cancer markers, which are soluble tumor-related substances in the blood, can be used to monitor the progress of tumor therapy. Although not yet widely available, a different diagnostic approach for cancer is tumor imaging. This consists of injecting the patient with tumor-specific monoclonal antibody labeled with a γ-ray emitting radioisotope. Tumors can then be detected by γ-ray cameras after the labeled antibody has targeted to the cancer cells (→Diagnostic Reagents). This methodology may soon be extended to the detection of other abnormalities, such as atherosclerotic plaques, blood clots, and sites of infection.

Therapy. Compared to the success of diagnostic monoclonal antibodies the development of therapy based on monoclonals has been disappointing.

Proposed therapeutic uses of monoclonal antibodies range from the replacement of conventional antisera (e.g., in passive immunization against rabies) to more speculative novel applications (e.g., in the control of autoimmune disease; see also →Immunotherapy and Vaccines, Chap. 6.). In practice only a single monoclonal antibody for therapy has received a product licence in the United States (Orthoclon, Ortho Pharmaceutical Corporation). Orthoclon is an antibody to T-lymphocytes that is used to suppress patients' immune response following kidney transplantation, thus reducing the incidence of organ rejection. Antibodies are in clinical trials in three main areas:

1) The treatment of cancer using antibodies to target radioisotopes.
2) The use of monoclonal antibodies linked to cytotoxic drugs or biological toxins such as ricin for "purging" bone marrow before transplantation to remove leukemic cells or T-lymphocytes that are responsible for Graft versus Host Disease.
3) Neutralization of noxious substances such as rabies virus, bacterial endotoxins, or Tumor Necrosis Factor.

Four major development areas may bring about more widespread introduction of therapeutic monoclonal antibodies:

1) The problem of making human monoclonal antibodies will be solved by the approaches described in Chapter 3. This will allow repeated administration of monoclonal antibodies without the adverse reactions currently experienced.
2) The limited access of monoclonal antibodies to tumors and the prolonged residence time in the blood will be improved by genetically engineering antibody fragments.
3) These "cut-down" antibodies may be further modified by replacing the non-antigen-binding parts of the antibody molecule with other biologically active proteins or protein fragments.
4) Improvements in expression systems and large-scale production and purification of monoclonal antibodies will drastically reduce their manufacturing cost, particularly if the production of monoclonal antibody fragments in microorganisms can become generally applicable [47], [48].

1. Introduction

Monosodium glutamate (MSG) is a monosodium salt of L-glutamic acid; it is used in huge quantities as a flavor enhancer throughout the world. L-Glutamic acid is one of the naturally occurring amino acids and occurs both in bound form as a constituent of proteins together with other amino acids, and also in the free form.

L-Glutamic acid was first isolated in 1866 by RITTHAUSEN [6] from the acid hydrolysate of wheat gluten, and its chemical structure was identified synthetically by WOLFF in 1890 [7]. In 1908, KIKUNAE IKEDA discovered the ability of the monosodium salt of glutamic acid to enhance the flavor of foods [8].

A kelp-like seaweed harvested around Japan, known as Konbu (*Laminaria Japonica*), has been used for centuries by Japanese cooks to improve the flavor of soups and certain other foods. IKEDA was curious why the taste of soup was enriched when its stock was prepared from konbu. He isolated 30 g of L-glutamic acid by extracting 40 kg of the kelp with hot water and discovered that glutamate was the substance which made the difference. Immediately, he filed a patent for the production of MSG as a new seasoning [9]. IKEDA developed a process to extract MSG from wheat flour. In 1909, MSG was first produced commercially under the trade name Ajinomoto.

2. Properties

Monosodium L-glutamate monohydrate [*142-47-2*], $C_5H_8NO_4Na \cdot H_2O$, M_r 187.13, crystallizes from aqueous solution at room temperature as rhombic prisms. Its crystal structure, determined by X-ray analysis, indicates that the sodium ions are coordinated octahedrally by four (3 α and 1 γ) carboxyl oxygen atoms and two water molecules [10].

The solubility of MSG is given by the following equation:

$$S = 39.06 + 0.108t + 0.0013t^2$$

where S is the concentration of MSG in wt % in a saturated solution at t °C [11]. Below −0.8 °C, MSG crystallizes as the pentahydrate [11]. The pH of a 3 wt % aqueous solution of MSG at 25 °C is 7.0.

Crystalline MSG is less hygroscopic than sodium chloride. The critical humidities of MSG are 96.0, 94.8 and 90.0 % at 20, 30 and 50 °C, respectively [12].

MSG loses its water of crystallization at 120 °C; intramolecular dehydration occurs at 155 °C. The decomposition temperature is 225 °C.

The α-carbon of glutamic acid is chiral. The specific optical rotation $[\alpha]_D^{20}$ of a solution of 10 g MSG in 100 ml of 2 N HCl is +25.16°. Besides the naturally occurring dextrorotatory L-glutamic acid, D-glutamic acid [*6893-26-1*] and the racemic mixture, DL-glutamic acid [*617-65-2*], are also known. D-Glutamic acid is

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a16_711

only found as a constituent of the peptideglycans of cell walls and of bacitracins (polypeptide antibiotics) produced by some microorgansims (e.g., *Bacillus subtilis*). The unique flavor enhancing characteristics are possessed only by the L-form.

Monosodium glutamate does not racemize even at 100 °C in neutral solution. At 100 °C, a pH above 8.5 results in thermal racemization. Racemization is also brought about by a microbial racemase. The racemase that is specific for glutamic acid is found in *Lactobacillus fermenti*.

The α-amino and γ-carboxyl groups of L-glutamic acid form an intramolecular peptide bond upon dehydration.

The equilibrium of this reaction favors the formation of 2-pyrrolidone-5-carboxylic acid [*98-79-3*] (PCA) when the pH is weakly acidic or weakly basic. At neutral pH, the rate of dehydration is at a minimum. Under strongly acidic or alkaline conditions, the equilibrium favors hydration of PCA [13]. Under normal cooking conditions, neither racemization nor dehydration occurs.

The threshold value (minimum perceptible concentration) of MSG is 0.03 %, which is smaller than that of sodium chloride (0.2 %) or sucrose (0.5 %). The flavor enhancing activity of MSG is synergistically increased in the presence of 5′-inosinate [*131-99-7*] and 5′-guanylate [*85-32-5*].

L-Glutamic acid is classified as a nonessential amino acid. It is a key substance in the nitrogen metabolism of amino acids. Inorganic nitrogen is incorporated by reductive amination of 2-oxoglutarate [*328-50-7*] to L-glutamate, catalyzed by glutamate dehydrogenase. There are many kinds of aminotransferases in various organisms that transfer an amino group from an amino acid to 2-oxo-acid, and many of them use the glutamate/ 2-oxoglutarate pair as the amino donor/acceptor. L-Glutamate is also the direct precursor of L-glutamine [*56-85-9*], the neuro transmitter γ-aminobutylic acid (GABA) [*56-12-2*], γ-carboxyglutamate [*53861-57-7*] in calcium binding proteins, and the tripeptide glutathion [*70-18-8*] [14].

3. Production

Classical Processes. From 1909, when industrial production of MSG started, until 1965, when production by the extraction process ceased, wheat gluten separated from wheat flour was the main raw material. It was used because of its high content of L-glutamic acid (ca. 25 wt %). After 1934, defatted soybean flake was also employed as raw material, since it did not produce starch as a byproduct.

The raw material is hydrolyzed by heating with hydrochloric acid. After concentration under reduced pressure and addition of concentrated hydrochloric acid, the hydrolysate is cooled to crystallize L-glutamic acid hydrochloride [*138-15-8*]. L-Glutamic acid can easily be separated from other amino acids in the form of its hydrochloride because of its very low solubility in concentrated hydrochloric acid. The hydrochloride is collected by filtration and then dissolved in warm water and the solution filtered to remove insoluble humic materials, which are mainly formed by the reaction of amino acids with carbohydrates. The pH of the filtrate is adjusted to 3.2, the isoelectric point of L-glutamic acid, with sodium hydroxide or ammonia to precipitate crystals of L-glutamic acid. The yield of L-glutamic acid is high because of its low solubility in water (0.864 g per 100 mL at 25 °C).

The crude L-glutamic acid crystals are suspended in water and neutralized with sodium hydroxide. The solution is decolorized with activated charcoal to give a clear solution and concentrated to crystallize MSG crystals. The crystals of MSG are then separated from the mother liquor by centrifugation and dried for packaging.

In the United States and some European countries, PCA, contained in byproducts of the sugar beet industry, e.g., Steffen's waste or vinasse, has been used as raw material for MSG. The PCA is hydrolyzed at weakly alkaline pH and moderate temperature (e.g., pH 10.5 – 11.5 at 85 °C for 2 h) [15] to avoid racemization. The pH of the hydrolysate is adjusted to 3.2 with a mineral acid to precipitate crystals of L-glutamic acid. The L-glutamic acid is transformed to MSG as described above.

Fermentation Processes. In the early 1950s, DAGLEY et al. reported the excretion of small amounts of amino acids in the culture medium of *Escherichia coli*. They found that addition of excess ammonium salts resulted in increased amino acid production [16]. In 1957, KINOSHITA and co-workers discovered bacteria that accumulate large quantities of L-glutamic acid [17]. The method of KINOSHITA et al. gave yields of L-glutamic acid of about 30 % using *Micrococcus glutamicus* (later renamed *Corynebacterium glutamicum*), which was immediately applied for the industrial production.

Bacteria that produce L-glutamic acid are widely distributed in nature, as shown in Table 1 [18]. Most of these bacteria are Gram-positive, non-spore-forming, non-motile, and require biotin for growth.

Table 1. Microbial strains producing l-glutamic acid

Genus	Species
Corynebacterium	*C. glutamicum, C. lilium, C. callunae, C. herculis*
Brevibacterium	*B. divaricatum, B. aminogenes, B. flavum, B. lactofermentum, B. saccharolyticum, B. roseum, B. immariophilum, B. alanicum, B. ammoniagenes, B. thiogenitalis*
Microbacterium	*M. salicinovolum, M. ammoniaphilum, M. flavum var. glutamicum*
Arthrobacter	*A. glubiformis, A. aminofaciens*

For industrial production of MSG, molasses and starch hydrolysate are generally used at present as raw materials. The accumulation of L-glutamic acid is governed not by its biosynthesis in the bacterial cells but by its secretion. Biotin is one of the vitamins essential for cell growth, but a biotin concentration in the culture medium sufficient for cell growth makes the cell membranes impermeable for L-glutamate and results in poor accumulation. The critical biotin content of the cells for L-glutamic acid production is 0.5 µg/g dry cells. Thus the accumulation of L-glutamic acid is at a maximum when the biotin concentration is suboptimal for maximum growth. Therefore, raw materials that are rich in biotin, such as beet molasses and cane molasses, could not be used until the discovery of the biotin-inhibiting effects of C_{16}–C_{18} saturated polyoxyethylene fatty acid esters. Limiting the amount of biotin is believed to cause incomplete biosynthesis of oleic acid, which results in a decrease of the phospholipids in the cell membrane and makes the membrane permeable [19].

Ammonium salts and urea are used as nitrogen sources for both microbial growth and product formation. The culture medium becomes acidic because of assimilation of ammonium ions and formation of L-glutamic acid. Gaseous ammonia is used advantageously to maintain neutral pH and to avoid dilution of the broth, because it contains neither hydroxyl ions nor water.

As the biosynthesis of L-glutamic acid is an aerobic process, the pressure of dissolved oxygen must strictly be kept above 1 kPa by aeration and agitation in the fermenter.

Genetically, many attempts have been made to improve the productivity of the process. L-Glutamic acid is synthesized biochemically through the glyoxylate cycle as an oxaloacetate generating system without carbon dioxide fixation, and through phosphoenolpyruvate [*138-08-9*] to form oxaloacetate [*328-42-7*] with carbon dioxide fixation (Fig. 1). The use of several mutants with high phosphoenolpyruvate carboxylase activity [20] or low isocitrate lyase activity [21] led to improved productivity of L-glutamic acid and increased the extent of carbon dioxide fixation. Application of genetic engineering techniques for further improvement is also in progress [22–25].

Figure 2 shows a typical large scale fermentation system equipped with automatic control which can be performed by computer aided systems [26].

Progress in fermentation technology has made it possible to raise the accumulation and the yield of L-glutamic acid above 100 g/L and 60 %, respectively. The pH of the fermentation broth is adjusted to 3.2 to recover L-glutamic acid crystals, which are then converted to MSG by the same method as in the extraction process.

4. Uses

Seasoning. MSG is widely used as a long-established seasoning or flavor enhancer to improve the palatability of foods. The effect of MSG is due to its characteristic taste, umami. Developments in food sciences, including electrophysiology, biochemistry, psychophysics, food chemistry, and nutrition, have provided evidence that umami should be re-

Figure 1. (A) Biosynthetic pathway of L-glutamic acid through the glyoxylate cycle as an oxaloacetate generating system without carbon dioxide fixation; (B) Biosynthetic pathway of L-glutamic acid through phosphoenolpyruvate as an oxaloacetate generating system with carbon dioxide fixation.

garded as a basic taste independent from the traditional four basic tastes: sweet, sour, salty, and bitter [27]. Umami cannot be composed from the classical four basic tastes and is essential to describe the human taste modality in general. Glutamates are ubiquitous in foods such as human milk, tomatoes, cheese, and seaweed. Other umami substances, i.e., 5′-ribonucleotides such as inosinate and guanylate are found in meats, fish, vegetables, and mushrooms. When glutamates and nucleotides coexist, a very strong synergistic effect occurs and umami is dramatically enhanced [28]. When foods contain umami substances under the taste threshold, just a small amount of additional umami substance makes a remarkable contribution to the flavor.

The taste threshold of MSG is around 0.03 % in aqueous solution. The umami intensity increases linearly according to the logarithm of the concentration of MSG. MSG does not enhance the taste of other basic taste substances nor is it enhanced by them. The synergistic effect of MSG with 5′-ribonucleotides is expressed as $y = u + \gamma uv$ where u and v are the respective concentrations of MSG and 5′-ribonucleotides, y is the equivalent concentration of MSG alone, and γ is a constant: 1200 for disodium 5′-inosinate (IMP) and 2800 for disodium 5′-guanylate (GMP) [29]. In some commercial umami seasonings, IMP or GMP or both are added to take advantage of the synergism with MSG.

Monosodium glutamate works well in a wide variety of foods, notably in meats, seafoods, vegetables, soups, stews, and chowders. Alcoholic beverages, fruits, and confectionery are not considered to be improved by addition of MSG. The effect of MSG on smell (or aroma) is negligible. When MSG or umami taste is added to an appropriate food at an appropriate level, certain flavor characteristics of food, such as body, mouthfulness, mildness, and continuity of flavor are increased. Thus the flavor appeal of foods is improved [30].

Although MSG increases the palatability of food, it is not always palatable by itself. When MSG is tasted in crystal form or in simple solutions, it does not cause a pleasant sensation. It gives a pleasant sensation only in flavored solutions or in actual foods [31]. Another important property of MSG is the concentration dependence of its pleasantness rating. An excess of MSG causes an unpleasant sensation, and thus the amount of MSG that is added to foods should be limited [31]. The desirable usage level of MSG depends on a number of properties of the food, including the contents of original umami substances, flavor intensity, flavor quality, density, and others. Results of extensive taste studies indicate that the optimum MSG level in food ranges from 0.1 to 0.8 wt %, varying from food to food.

In most cases, MSG is used in combination with salt. A relation between the levels of MSG and salt and palatability of foods has been clarified. The lower the salt concentration, the higher the MSG concentration required to maintain the palatability and vice versa. When umami substances are added to meals, the amount of salt can be reduced; thus the total sodium intake can be reduced without a decrease in the palatability or degree of satisfaction.

Umami is considered to be a universal taste sensation for mankind. An ethnic comparison of taste sensitivity has shown that there is no difference in the thresholds of MSG and IMP between Japanese and Euro-American Caucasians [32]. Even in the very first hours of extrauterine life, the human neonate responds to MSG with facial expressions. When a vegetable soup containing MSG was fed to neonates, they showed more pleasant and satisfied facial and oral expressions than for soup without MSG [33].

Industrial Uses. Depending on the pH, glutamic acid can be used to neutralize acidic or basic compounds. For example, arginine glutamate is used as a pharmaceutical and raw material for cosmetics. The reaction of glutamic acid with hydrochloric acid affords glutamic acid hydrochloride, which is used as a gastric acidifier. Glutamic acid's properties as an amphoteric electrolyte are exploited in chelating agents, buffers, and builders for detergents.

The sodium salt of pyroglutamic acid, which is obtained by dehydration of glutamic acid followed by neutralization with sodium hydroxide, is very hygroscopic and is used as a component of a natural moisturizing factor for human skin and as a numectant for cosmetics [34]. A polymer of methyl glutamate is used as a coating agent for synthetic leather [35], [36]. A condensate with formaldehyde is useful as a retarder for plaster [37]. The *N*-acylated compound pro-

duced by reaction with a long-chain fatty acid is an anionic surfactant and is popularly used for skin and hair cleansers due to its mildness and high safety [38]. The dibutylamide of this *N*-acylglutamic acid gelatinizes nonpolar oils and can be used as a recovering agent for spilt marine oil [39].

5. Toxicology

Glutamic acid is one of the most abundant amino acids in the diet and constitutes 10 – 35 % of the amino acids in proteins. Many foods also contain free glutamate, which contributes to their taste. MSG is metabolized in the same way as naturally occurring free glutamate and glutamate derived from the digestion of protein. After oral ingestion, glutamate is absorbed from the intestine by an active transport system. During this process, a large proportion is metabolized to alanine and 2-oxoglutarate, which enters the tricarboxylic acid cycle. Glutamate is further metabolized in the liver to give glucose, lactate, glutamine, and other amino acids. Consequently, blood glutamate levels do not rise significantly unless very large concentrated doses are administered. The blood glutamate level rises transiently when a large concentrated dose is ingested on its own, but the co-ingestion of foods that contain metabolizable carbohydrates increases its metabolism and eliminates or greatly attenuates this rise. Human infants, including premature infants, metabolize glutamate similarly to adults [40], [41].

The acute toxicity of MSG is low; the LD_{50} values, when administered in different ways to different animals, are shown in Table 2. The oral LD_{50} extrapolated to humans would represent a single dose of over 1 kg for a person weighing 70 kg; the oral LD_{50} for sodium chloride in rats is 3.75 g/kg [43].

The concentration of glutamate is higher in the brain than in the blood. In monkeys, guinea pigs, rats, and mice, glutamate levels in the brain remain unchanged after the administration of large oral doses of MSG. When large amounts of MSG are forcibly administered to some infant animals by injection, brain and retina lesions can occur. There are species- and age-dependent differences in sensitivity to these neuronal lesions. In mice, the most sensitive species, the newborn are sensitive but the adults are not. Hamsters and guinea pigs are less sensitive, dogs are not sensitive, and in nonhuman primates, even the injection of MSG into the foetus does not produce neuronal lesions. When MSG is administered orally in the diet or drinking water, neuronal lesions do not occur even in infant mice, except following dehydration by water deprivation.

The main use of MSG is as a food additive, and so its toxicity when used in the diet is the most important aspect of its safety in use. Both short term and chronic toxicity studies on MSG in the diet of several species at doses of up to 4 % (ca. 6 – 8 g per kilogram body weight per day) of daily food intake showed no specific toxic effects, and no evidence for carcinogenicity or mutagenicity. Reproduction and studies of up to three generations have not revealed any adverse effects of dietary MSG ingestion, with fertility, gestation, viability, and lactation indices and the pre- and post-weaning performance of offspring being unaffected. In primates, it has been found that the placenta serves as an effective metabolic barrier to the transfer of glutamate from the mother to the foetus, and in humans the glutamate level in mother's milk is hardly affected by oral ingestion of large doses of MSG [40], [41], [44].

Since 1968, much publicity has been given to a postprandial symptom complex, involving facial pressure, chest pain, and a burning sensation, called "Chinese restaurant syndrome" (CRS). Initial reports claimed that the symptoms occurred after eating at Chinese restaurants and suggested that MSG was the causative agent. However, a large scale epidemiological survey has found that only 0.2 % of the surveyed population could be classified as having experienced the syndrome after ingesting Chinese food, and controlled double-blind studies have failed to show an unequivocal relationship between CRS and the consumption of MSG. The symptoms are subjective and can be experienced after the ingestion of substances not containing MSG, such as orange juice, coffee, and spiced tomato juice. Although the administration of large concentrated doses of MSG in the laboratory can provoke CRS-like symptoms in some people, when self-proclaimed CRS sufferers were given MSG or a placebo in a double-blind test, they failed to respond selectively to MSG [40], [41], [45], [46].

Table 2. LD_{50} (g/kg body weight) of MSG in various species [41], [42]

Species	Route of administration			
	Oral∗	Subcutaneous	Intraperitoneal	Intravenous
Mouse	13.0, 16.2 17.0, 19.2	8.3	6.1	3.5
Rat	16.5, 16.6 19.9	6.0	5.2	3.3
Guinea pig			15.0	
Rabbit	> 2.3∗∗			

∗ Multiple values represent LD_5^0 data obtained by different researchers.
∗∗ Glutamic acid.

When used normally as a food additive, MSG does not show any harmful side effects, and in 1987 the World Health Organization (WHO) and the Food and Agricultural Organization (FAO) of the United Nations established the acceptable daily intake (ADI) for L-glutamic acid and its monosodium, potassium, ammonium, calcium and magnesium salts as being 'not specified'. This means that on the basis of the available data, the total daily intake of the substance, arising from its use at the level necessary to achieve the desired effect and from its acceptable background in food, in the opinion of the joint FAO/WHO expert committee on food additives (JECFA), does not represent a hazard to health, and so it was not deemed necessary to establish a numerical limit [41].

6. Economic Aspects

The annual production of MSG was estimated at 350 000 t worldwide in 1988 [47]. The world capacity for the production of MSG is more than 500 000 t/a [47] including the People's Republic of China and it is still increasing. The international price of MSG is $ 1500 – 1800 per tonne. The demand for MSG is expected to increase in developing countries.

1. History

1.1. The Spark Ignition (Otto) Engine and Its Fuel

In 1876 NIKOLAUS AUGUST OTTO developed a stationary, single-cylinder, four-stroke engine, that ran on coal gas. This invention, which was later named after him, set a development in motion that substantially shaped the industrial age and has not yet come to a halt [1, 2]. About ten years later the four-stroke engine was first used to drive vehicles (Daimler and Maybach automobiles, Benz patent car). The first vehicle engines ran on so-called *light gasoline* which had a low density (< 700 kg/m^3) and a very low final boiling point (ca. 85 °C). Light gasoline was available as a cleaning agent at pharmacies and could be evaporated in the first surface carburetors. The development of spray nozzle carburetors finally enabled the use of *straight-run gasoline* with a broader boiling range and higher final boiling point [3]. A higher proportion of crude petroleum could thus be used as a fuel, and the rising demand for gasoline could be satisfied.

After the development of a reliable mixture preparation system, attention focused on the further improvement of the engine power by increasing the compression ratio (from ca. 1918 on). The increase in compression ratio was shown to be limited by abnormal combustion, so-called engine knock, which can damage the engine. Since it was observed that knocking combustion can be related to gasoline formulation, systematic research began to improve the knock resistance of fuels.

Discovery of the strong antiknock effect of tetraethyllead by MIDGLEY and BOYD in 1922 was a milestone in the development of gasolines. A little later, refinery conversion processes were established that allowed the demand for gasoline to be met by improving the yield, and which also led to a further improvement in antiknock performance, so-called octane quality (→ Oil Refining). The further advances in the development of engine technology and in the quality of gasoline were mutually dependent. From 1950 on, increasing attention was given to the further improvement of gasoline by the addition of small quantities of highly active additives (see Section 5.1).

Since 1970, measures for improving the environmental compatibility of automotive use have become increasingly important worldwide. The first step was the successive reduction in the lead additive content of gasolines. Later, completely unleaded gasolines were developed, which were a prerequisite for the introduction of catalytic converters.

The reduction of sulfur content in gasoline has occurred more recently and it is still ongoing. This measure improves the efficiency and durability of modern exhaust gas aftertreatment devices and reduces the emission of sulfur compounds. In this context "sulfur free" gasolines (less than 10 ppm sulfur) have been made available on a wider scale. In countries with tax incentives for "sulfur free" fuels like Germany this fuel quality has a high market share. The limitation of benzene, other aromatics, and olefins concentration in gasoline is intended to reduce the resulting-post catalyst exhaust emissions. The worldwide rising demand for oil products has led to noticeable price increases and because of this development alternative fuels or fuel components (e.g., alcohols from biomass) have again achieved a certain significance.

1.2. The Diesel Engine and Its Fuel

The diesel engine, patented in 1892 by RUDOLF DIESEL, is characterized by self-ignition of the fuel [4]. Self-ignition is achieved by compressing the incoming air to such an extent that the resulting temperature increase is sufficient to ignite the fuel.

In the development of his engine, DIESEL's aim was an engine operation as close as possible to the Carnot cycle – which gives the highest theoretical efficiency – with the result that the first diesel engine built in 1893 at the Maschinenfabrik Augsburg Nürnberg AG (MAN) operated at a hitherto unachieved efficiency of 26.2 %. The power of this engine was 17.8 metric horsepower (13.1 kW) at 194 rpm, and it ran on a mixture of gasoline and lamp oil. After 1897, experiments with other fuels started, which had little success at first.

The injection of small quantities of fuel at high pressure caused the greatest problem in the initial phase of the development. Blowing the fuel in with compressed air, which was tried at

first, did not solve the problem satisfactorily. High-pressure liquid injection was developed in 1910; and in 1927, large-scale production of fuel injection systems started and the way was opened for broad expansion of the diesel engine. MAN and Daimler – Benz introduced the diesel engine to commercial vehicles in 1923 – 1924. About 12 years later, Daimler – Benz introduced the first passenger car diesel engine (type 260 D, 2.6 L, 45 metric horsepower at 3000 rpm).

Even the first diesel engines were often run on the so-called gas-oil fraction of crude petroleum (boiling range 200 – 350 °C). This type of fuel, which is provided in sufficient quantity mainly by crude oil distillation at moderate production cost is basically still used today, because of its suitable ignition quality (see Section 3.2.1).

In addition to high ignition quality (cetane number; see Section 3.2.1), cold flow properties and low tendency toward coking and sooting became important at an early stage.

During World War II, large quantities of diesel fuel were produced from coal in Germany. Mixtures of components of low ignition quality (tar oil) and very high ignition quality (from the Fischer – Tropsch synthesis) were used [3].

Because of the increasing demand for light oil products that followed World War II, gas-oil fractions from conversion processes have also been used in diesel fuel. However, these components are generally less suitable because of their lower ignition quality. For environmental protection and improved engine performance a number of measures were taken to raise the diesel fuel quality. For example, the maximum permitted sulfur content of diesel fuel was lowered stepwise from 1.0 (1955 in Germany) to 0.035 mass % (2000) and further to 0.005 mass % (2005) in Europe. Also a fuel quality with a sulfur content less than 0.001 mass % (sulfur free) must be available. The maximum permitted sulfur content in different areas is given below:

United States	0.001 (max average of refinery production) mass %
EU	0.005 and 0.001 mass %
Japan	0.0015 mass %

The reduction of sulfur in the diesel fuel helped also in the introduction of particulate traps in the exhaust systems.

Synthetic components with ultra-high ignition quality available from, e.g., natural gas synthesis (basicly Fischer-Tropsch synthesis with a newly developed catalyst) are used in some markets to formulate a diesel fuel with superior quality. Also high-quality components produced from biomass will shortly be available in limited quantities for commercial use.

Reliable engine operation and a reduction in exhaust gas emissions is also the primary aim in the treatment of diesel fuels with multifunctional additives, which has come into increased use from 1985 onwards. In addition, acceptability of diesel fuels could be improved (foaming, odor; see Section 5.2).

2. Engine Technology

2.1. Otto Engines

The basic principle of the spark ignition (Otto) engine–a combustion engine with timed ignition from an external source – can be realized in a number of variants with different types of fuel metering and mixture preparations [5].

The most frequently used type is the *four-stroke* reciprocating Otto engine in which gas exchange processes during these four strokes are controlled by valves. The sequence of strokes is

1) intake of the fuel – air mixture,
2) compression of the mixture and timed ignition,
3) combustion and expansion (working stroke), and
4) exhaust of combustion gases.

To carry out one working stroke the crankshaft turns twice. The valves are operated by a camshaft connected to the crankshaft.

The *rotary engine* (frequently called the *Wankel* engine after its inventor) is a variant of the four-stroke engine. It differs from the reciprocating piston engine in its rotary piston and in the use of ports for control of the inlet and exhaust gases [6, 7]. The rotary piston engine has not been very successful up to the present, compared to the reciprocating engine because of its relatively high fuel consumption and exhaust gas emissions.

In the standard *two-stroke* Otto engine the gas exchanges are also controlled by ports (inlet, transfer, and exhaust ports) in the cylinder.

A working cycle is achieved with each rotation of the crankshaft, and high power output at low swept volume is achieved. However, in the two-stroke process, scavenging losses must be accepted that lead to relatively high fuel consumption and hydrocarbon-exhaust emission. The two-stroke engine is used only in small motorcycles, outboard engines and light-weight machines [8]. Technically advanced models controlled by valves can overcome many of the disadvantages normally associated with these engines to a certain degree. However, more stringent exhaust gas requirements will reduce the use of two-stroke engines in the future.

The Otto engine runs with throttled intake air (quantity governing) and an almost homogeneous, approximately stoichiometric fuel – air mixture. Traditionally, the composition of the mixture depended on the running condition of the engine: i.e., at full load and directly after cold start the engines operated with an excess of fuel (rich mixture) whereas under part load nearer to the stoichiometric mixture. For the preparation of the fuel-air mixture previously carburetors [9] were used.

Modern electronic fuel injection systems, are superior to carburetors with respect to performance, fuel consumption, and accuracy of mixture strength control necessary for the efficient use of three-way catalytic converters [10]. Carburetors were therefore gradually replaced by fuel injection systems. Latest development are the so-called direct injected engines, which offer optimum fuel efficiency [11]. The main advantage of this technology is the avoidance of throttling losses at part load conditions. Whereas conventional Otto engines run at fixed air-fuel ratio and adjust power at part load by reducing the cylinder charge by the throttle valve, direct injected engines run in this respect rather like a diesel with almost unthrottled cylinder charge and varying amounts of fuel injected. To ensure proper ignitability of very lean mixtures at low load a locally gasoline enriched layer of air – fuel mixture ("stratified charge") must be created.

In the Otto engine the combustion process is started by an electric spark. Ignition occurs shortly before the piston has reached the top dead center and is advanced with increasing speed to allow a timed combustion beginning shortly before the top dead center [12].

To achieve the highest efficiency in the Otto engine, combustion induced by the ignition spark must develop in a controlled way under all operating conditions. If the resistance of the gasoline against autoignition, i.e., the octane quality of the fuel does not meet the octane number requirement of the engine, after compression by the piston either before or after ignition by the spark plug, autoignition of the yet unburned portion of the mixture occurs. This autoignition (engine knock) leads to a considerably higher combustion rate with a very sharp increase in pressure and temperature (Fig. 1). An anomalous combustion of this type manifests itself by a knocking or pinking noise. Whereas occasional knock that occurs on acceleration usually does not damage the engine, permanently knocking combustion at high speeds and loads over a longer period increases the risk of engine damage. Modern engine knock sensors allow safe engine operation even if gasolines of varying octane qualities are used, because they adjust the spark timing according to octane quality. However, gasolines with low octane quality require retarded ignition which leads to efficiency losses and, e.g., higher exhaust gas temperatures.

Figure 1. Combustion in the Otto engine
a) Without ignition; b) Normal combustion; c) Knocking combustion; d) Top dead center

Apart from design parameters the octane number requirement of an Otto engine varies with the engine speed and the load. Furthermore increasing deposit formation in the combustion chamber with increasing milage can raise the octane number requirement [13]. In designing an engine on the basis of a particular type of fuel, a safety margin must therefore be provided, to avoid knocking combustion even under unfavorable conditions.

2.2. Diesel Engines

The diesel engine differs from the Otto engine in the heterogeneous composition of its mixture and the self-ignition of the fuel. The temperature necessary for self-ignition is produced in the compression stroke, in which compression of air to ca. 3.0 – 5.5 MPa leads to temperatures of 700 – 900 °C. Fuel is injected into the heated air of the combustion chamber shortly before the end of the compression stroke, where it self-ignites. In principle the diesel engine can be either of the four- or two-stroke type. In practice, four-stroke engines are found in the vast majority of vehicles, whereas a valve-controlled two-stroke process with precompressed air is used in large ship engines.

In the diesel engine, air is generally taken in unthrottled and the fuel – air ratio varies with the quantity of fuel injected (quality governing) thus leading to a very lean fuel – air mixture ($\lambda > 1.3$, for definition of λ, see → Automobile Exhaust Control).

Two types of combustion systems have been developed for the diesel engine that differ in the preparation of the combustible gases [14]. *Direct injection* is characterized by a one-piece combustion chamber, into which fuel is injected without further preparation. Indirect injection is characterized by a two piece combustion chamber and was a mechanical solution to control the rate of combustion.

One of the main problems of the early diesel engines was the control of the combustion rate. Depending on the fuel and engine parameters ignition was often delayed and the subsequent rate of combustion more rapid than desired for best efficiency, low noise and emissions, etc. In those days before the development of modern electronic control units, various mechanical solutions were available, such as divided combustion chambers or specific mechanically controlled injection spray patterns to adjust the rate of combustion. Very common, especially for passenger car diesel engines, were concepts with divided combustion chambers, so called indirect injection engines (IDI engines). These *precombustion chamber* processes, such as the *swirl chamber* and *prechamber* processes, have a two-piece combustion chamber. Fuel is injected into the precombustion chamber, partially homogenized with air, and self-ignited. Partially oxidized combustible gases and evaporated fuel reach the main combustion chamber via connecting channels and burn there after further mixing with air. Indirect injection engines were used predominantly in passenger cars. Their engine noise is less harsh, but their fuel consumption is higher than that of the direct injection diesel engine. The split combustion chamber gives rise to pumping losses which impair the efficiency of precombustion chamber engines. This is also brought about by their higher compression ratio leading to higher friction losses.

In contrast to the divided combustion chamber engine concepts with a one-piece combustion chamber, i.e., direct injection engines (DI engines), were originally used mainly for heavy-duty transport and machinery. Their undivided combustion chamber allows higher engine efficiency. In modern direct injection engines sequentially electronically controlled high-pressure fuel injection systems allow optimum combustion and pressure rise thus avoiding previous problems, e.g., noise or limited speed range. The so-called *common rail technology* allowing high injection pressures is now well implemented for passenger car diesel engines.

The compression ratio of direct injection engines (ca. 15 – 17 : 1) lies near that optimum for most favorable total efficiency, which occurs at a compression ratio of ca. 15 : 1.

Figure 2. Combustion in the diesel engine
a) Noisy combustion; b) Normal combustion; c) Without combustion; d) Ignition delay 1; e) Ignition delay 2; f) Top dead center; g) Injection period

As mentioned before the diesel fuel is injected into the combustion chamber near the end

of the compression stroke shortly before the piston has reached the top dead center. The period between the beginning of the injection mode and the start of the combustion is called ignition delay. The length of ignition delay depends on ambient conditions, e.g., temperature, design and construction of the engine and the ignition quality of the diesel fuel. Optimum engine operation, necessary for high efficiency, low noise, and exhaust emissions, requires short ignition delay and therefore high diesel fuel ignition quality, i.e., a high cetane number. Prolonged ignition delay causes an unacceptable steep pressure rise causing, e.g., high noise and nitrogen oxide emissions (see Fig. 2) [15, 16].

3. Fuel Composition and Engine Efficiency

Because of the different modes of operation of Otto and diesel engines (see Chap. 2), completely different requirements exist for gasoline and diesel fuels and their composition. The effects of important fuel properties on the performance of engines are discussed below. The standardization of minimum requirements derived from them is described in Chapter 6.

3.1. Quality Aspects of Gasoline

The most important quality criteria for gasoline are its resistance against autoignition (engine knock), i.e., octane quality, the evaporation properties to provide an ignitable air – fuel vapor in the combustion chamber, environmental acceptability and low toxicity, and also cleanliness and stability. While all of these aspects are influenced by the main gasoline components and thus by refinery technologies, some can also be improved by additives, i.e., small proportions of organic substances, added to the gasoline mainly at the end of the production process and prior to delivery to the service stations.

3.1.1. Octane Quality

High octane quality is required to allow knock-free combustion in high compression engines to enable optimum engine efficiency. While the engine efficiency can be raised generally by increasing the compression ratio – leading to a higher octane requirement of the engine – the production of matching high octane fuels is connected with a higher energy demand in the refinery. The overall optimum efficiency (taking into account engine and refinery) is obtained with the most widely used premium and super gasolines with research octane numbers of 95 to 100 and engines designed for that octane quality.

The octane level of a gasoline depends on that of the individual refinery streams and on that of other, e.g., oxygen containing components such as ethers or alcohols. The octane quality of gasoline is described by the *octane number.* The octane number of a gasoline is determined by comparative measurements of its octane quality and that of binary mixtures having variable concentrations of *n*-heptane (low octane quality) and 2,2,4-trimethylpentane (isooctane; high octane quality). By definition the octane number of *n*-heptane is 0 and that of isooctane is 100. The octane numbers of mixtures are given by their percentage by volume of isooctane; octane numbers > 100 can be determined with lead-containing isooctane or toluene-containing mixtures.

Octane number determination (e.g., according to EN 25164 or EN 25163) is carried out in single-cylinder, four-stroke test engines specially developed for the purpose. The CFR (Cooperative Fuel Research) engine is most widely used worldwide. The test engines have a mechanically adjustable compression ratio. This ratio is raised during octane number measurement of a fuel until a certain standardized level of knocking, shown by a so-called knock meter, is obtained. The gasoline's octane number is determined by finding the *n*-heptane – isooctane mixture that gives the same knock level. Determination of the octane number is carried out under two different running conditions:

1) **Determination of the research octane number (RON)**: according to EN 25164, ASTM D 2699, in which comparatively mild conditions are used (600 rpm, no prewarming of the mixture, constant ignition timing).
2) **Determination of the motor octane number (MON)**: according to the EN 25163, ASTM D 2700, in which a higher mechanical and thermal load is used (900 rpm, prewarming of

the mixture to 150 °C, and variable ignition timing).

Because of the more severe test conditions the MON is usually lower than the RON; the difference between both is called *sensitivity* [17]. The RON describes the knocking performance of a gasoline at low and medium engine speeds ("acceleration knocking") whereas the MON defines the knock behavior under high speed and load ("high speed knocking"). The knock rating of a fuel is generally sufficiently characterized by its RON and MON. Historically it was necessary to use an additional characteristic, the *front octane number* (FON) describing the RON knock rating of the low boiling fuel components. An insufficient FON leads to knocking during acceleration, particularly in carburetor vehicles. This problem does no longer exist in fuel-injected vehicles.

For research and development purposes it is also possible to measure the octane quality in vehicle Otto engines under normal road use. The so-called *road octane number* gives information on the octane quality in vehicle Otto engines under normal road use. The road octane number is specifically related to the vehicle type and is also affected by driving conditions and weather. Usually the road octane number is given by an expression of the type a RON + b MON + c, where a, b, and c are constants that depend on the vehicle. The road octane number of a gasoline lies between the RON and MON, nearer the RON under acceleration conditions and approaching the MON under constant speed.

3.1.2. Volatility

Fuel volatility, expressed by distillation behavior (EN ISO 3405, ASTM D 86) and vapor pressure, controls the formation of an ignitable air – fuel mixture and the ability of the engine to start and run under cold and hot conditions. For safe operation the fuel must have a balanced distillation performance [13]. A certain proportion of volatile fuel components are needed for trouble-free performance at low temperature. An excess of these components leads, however, to hot fuel handling problems with a warm engine or high ambient temperature (see Fig. 3). To ensure trouble-free engine running, the boiling characteristics are usually matched to climatic conditions and change during the year. An excessively high final boiling point can cause deposit formation and lubricant dilution, and consequently engine wear.

Gasoline volatility also controls exhaust gas emissions and evaporative emissions. Vehicle design elements such as the activated carbon canister have of course a larger effect on these emissions. However, in a vehicle of given design the volatility of the fuel can contribute to guarantee low emissions. For example, a sufficiently high vapor pressure and high volatility ensures low exhaust gas emissions at low ambient and engine temperatures and sufficiently low vapor pressure reduces evaporative losses at high ambient and fuel system temperatures.

Figure 3. Significance of gasoline distillation properties for engine performance and emissions [19]

Table 1. Summary of effects of gasoline properties on emissions in noncatalyst cars (source: EPEFE program)

	Change	Lead	CO	HC exhaust	HC evaporation	NO_x	Benzene	Butadiene	Aldehydes

** E 150 = % evaporated at 150 °C.

3.1.3. Fuel Composition to Reduce Toxicity and Exhaust Emissions

Some of the gasoline constituents, especially benzene and previously used lead antiknock additives, are toxic and other components can form toxic materials during combustion. Both benzene and alkylleads were formerly used to improve the octane quality of gasolines. Their maximum allowed concentration was legally reduced stepwise. While lead has completely disappeared from gasoline in most countries also because of its poisoning effects on exhaust gas catalysts, benzene content has been restricted in Europe initially to maximum 5 vol % and since the year 2000 to 1 vol %. The major German oil companies produced their top quality Super Plus since 1995 already with benzene concentrations below 1 vol % on a voluntary basis. Benzene has not been used as an active blending component for a long time. It is extracted from the relevant gasoline components (e.g., reformate) mainly by distillation and also its formation in the catalytic reformer is minimized by extraction of "benzene precursors" in the reformer feed material.

To keep the octane quality of gasolines without lead and benzene above the standardized level, contents of other nontoxic materials were increased, namely of isomerates, higher aromatics, and to some extent ethers (→ Methyl Tert-Butyl Ether) and alcohols.

Ideally the gasoline is combusted completely to water and carbon dioxide, however, in practice other unwanted components are emitted because a small proportion of the gasoline (usually less than 1 %) leaves the combustion chamber unburned, e.g., because of quenching at the combustion chamber surfaces, or partly oxidized due to the high pressures and temperatures. Apart from carbon monoxide, unburned hydrocarbons, and nitrogen oxides, other toxic substances such as aldehydes, benzene, and 1,3-butadiene are emitted at very low concentrations. All of these are oxidized or reduced by the exhaust gas catalysts by more than 95 %. Their residual concentration can be influenced by gasoline composition and hence by the gasoline formulation in the refinery. Gasolines forming less toxic and environmentally harmful material have been called "reformulated gasolines".

The effects of gasoline properties and composition on exhaust gas and evaporative emissions have been studied in a wide range of modern vehicles, partly in joint motor – oil industry projects, (e.g., auto – oil programs) in the US and in Europe. The results of the European program are summarized in Tables 1 and 2 [20].

The reduction of sulfur and benzene has a clear-cut positive effect. The other measures, e.g., the reduction of total aromatics, the increase of mid-range volatility and the use of methyl *tert*-butyl ether have positive effects on some of the emission components but negative on others. This applies also to the reduction of vapor pressure (reduction of butane), which reduces the evaporative losses but increases emission of CO_2 and unburned hydrocarbons under cold start conditions.

A further objective is to reduce the formation of ozone and smog that occurs as a result of

Table 2. Summary of effects of gasoline properties on emissions in catalyst cars (source: EPEFE program)

	Change	Lead	CO	HC exhaust	HC evaporation	NO_x	Benzene	Butadiene	Aldehydes
Add oxygenate	0.0 to 2.7 mass % O_2	0	▼▼	▼	0 – ▲	+ 0	0	0	▲▲

Reduce sulfur	300 to 100 ppm	0	▼?	▼?	0	▼?	▼?	▼?	▼?
Reduce Reid vapor pressure	70 to 60 kPa	0	0	– 0	▼▼	0	0	0	0
Increase E 100*	50 to 60 %	0	+ 0?	▼?	0	0	0	0	0
Increase E 150**	85 to 90 %	0	0	▼▼	0	▲?	0	▼?	▼?

0 = no effect. ± 0 = −2 to +2 %. ▼ or ▲ = 2 – 10 % effect. ▼▼ or ▲▲ = 10 – 20 % effect. ▼▼▼ or ▲▲▲ = > 20 %. ? = insufficient information.
* % evaporated at 100 °C.
** % evaporated at 150 °C.

photochemical reactions between hydrocarbons and nitrogen oxides. The ozone forming potential of hydrocarbons differs depending on their structure and size. Thus, the composition of the unburned hydrocarbons can be optimized by the composition of the gasoline to reduce the ozone forming potential of evaporative losses and exhaust emissions. As an example the reduction of the highly reactive olefins in the fuel is a measure to reduce the ozone forming potential, however olefins are desired fast burning gasoline components which are also readily converted in the exhaust gas catalysts.

The evaluation of the results of the above mentioned programs have led to the production of specific "reformulated gasolines" in some areas, e.g., California and to the stepwise introduction of more stringent gasoline specifications, e.g., in Europe, as listed below.

	2000	2005
Aromatics	42 vol %	35 vol %
Benzene	1.0 vol %	1.0 vol %
Olefins	18 vol % *	18 vol %
Sulfur	150 ppm	50 ppm and 10 ppm

* max. olefin content regular grade 21 vol %

In Germany some mineral oil companies had voluntarily introduced sulfur free gasoline qualities, e.g., Shell Optimax. Since 2005 at least one sulfur free gasoline must be available at the gasoline stations. Currently a tax incentive for sulfur free gasoline ensures that the majority of gasoline sold in Germany is sulfur free. Low and ultra-low sulfur levels can also be found in other countries, e.g., in Japan and in the US. Sulfur free gasolines (sulfur content less than 10 ppm) are required for new highly efficient exhaust gas aftertreatment systems especially for lean burn direct injection engines. The new specifications require changes to the refinery units including substantial investment.

3.1.4. Stability, Cleanliness, etc.

Problem-free gasoline storage, distribution, and vehicle/engine operation requires a practical freedom from water, acids, and foreign matter particles. The gasoline must have long term and high temperature stability in the presence of air, (oxygen) and must be neutral to metals and elastomers. A number of laboratory tests with specified maximum tolerable limits are used to define these properties (see Chap. 6). Some of these properties can be influenced by additives (see Chap. 5), e.g., water shedding, anticorrosion properties, oxidation stability. The long-term effect of fuel on elastomers in the fuel system is controlled by the selection of suitable materials by fuel system manufacturers. These materials have been tested in standardized and critical reference fluids.

3.1.5. Performance Additives

To ensure safe operation of the engine, high-quality gasolines contain special additives which ensure optimum inlet system cleanliness (see

Section 5.1.2) and prevent corrosion (corrosion inhibitors, see Section 5.1.1).

3.2. Quality Aspects of Diesel Fuels

The diesel combustion process requires a fuel, which in contrast to gasoline ignites easily. Ignition quality is therefore the main quality criterion of diesel fuel. Density is important as an indicator for fuel consumption. Cold flow performance, fuel lubricity, viscosity, stability, and cleanliness control mainly reliability of engine operation. All the above mentioned aspects together with sulfur content have effects on emissions. Fuel volatility is far less important than that of gasoline.

3.2.1. Ignition Quality

Since the fuel is not ignited by an external source in the diesel engine, good ignition performance of diesel fuel is an important criterion for its quality. Ignition quality is determined by characteristics of the components used in production of the fuel (see Section 4.2) and can be improved by additives (ignition improvers, cetane improvers, see Section 5.2.1).

The *cetane number* is used to describe the ignition quality of diesel fuels. Like the octane number, the cetane number is determined by comparative measurements in single-cylinder test engines (CFR swirl chamber engine (EN ISO 5165, ASTM D 613), or BASF prechamber engine) [21]. Mixtures of α-methylnaphthalene with very low ignition quality (cetane number 0) and cetane (*n*-hexadecane) with very high ignition quality (cetane number 100) are used as references. The cetane number of a reference mixture is given by the volume percentage of cetane in α-methylnaphthalene. For the determination of ignition quality the ignition delay (time interval between start of injection and start of self-ignition) is kept constant by varying the compression ratio of the engine depending on the test fuel quality.

The ignition quality of diesel fuels can also be calculated using the *cetane index* method (EN ISO 4264, ASTM D 4737). However the cetane index gives only an indication of the ignition quality of a diesel fuel without cetane improvers. This index is calculated by means of a complex formula based on density and distillation range. The formula is updated in regular intervals depending on changes in diesel fuel quality and production technology.

A high cetane number is advantageous for the ignition and starting behavior, the reduction of exhaust gas and noise emission ("clatter") [22, 23].

3.2.2. Density

The density of a diesel fuel (EN ISO 12185, ASTM D 4052) has a considerable effect on the engine performance. Because the quantity of fuel injected into an engine is metered by volume, the mass of fuel introduced into the engine increases with density. A higher fuel density leads to an enrichment of the fuel – air mixture which in principle yields a higher engine power output. On the other hand a high density increases also particulate emissions and black smoke [24]. The maximum density for diesel fuels was therefore reduced from 860 to 845 kg/m^3 in Europe.

3.2.3. Sulfur Content

Exhaust emissions, specifically particulates, are increased by the sulfur in the diesel fuel. In addition acidic combustion products arising from sulfur (sulfur oxides) can lead to engine corrosion. In Europe the maximum sulfur content had therefore been limited to 350 ppm from January 1, 2000 onward and was further reduced to 50 ppm by 2005. Furthermore, it was decided to make "sulfur free" diesel fuels (sulfur contents less than 10 ppm) generally available to allow the use of improved exhaust gas after treatment systems. A tax incentive in Germany for sulfur free diesel fuels led to a widespread availability of these fuels.

3.2.4. Cold Flow Properties

The composition of a diesel fuel affects its filterability at low temperature to a great degree. Particularly, *n*-paraffins with high ignition quality tend to form wax crystals at low temperature,

which can lead to clogging of the fuel filter. For this reason during winter periods the proportion of low boiling components such as kerosene and others with reduced concentration of *n*-paraffins is often increased in relation to higher *n*-paraffin-containing gas-oil fractions. Diesel fuels with filterability at very low temperatures, such as arctic fuels, consequently may have lower densities, viscosities, and also ignition performance than normal diesel fuels.

The low-temperature filterability of diesel fuel has been substantially improved since the 1970s by use of highly active flow-improving additives at reasonable costs [25]. The cold filter plugging point (CFPP), a laboratory test EN 116, gives an indication of the low-temperature behavior of diesel fuels (see Section 5.2.3). The cold flow performance of fuel components is also characterized by the cloud point, EN 23015, i.e. the temperature at which wax crystals begin to form. For fuels containing cold flow additives the cloud point has little relevance. However, it is used for the specification of eratic fuels as a safeguard with values 10 °C above the CFPP filterability.

3.2.5. Lubricity

The introduction of low and ultra-low sulfur fuels initially led to severe problems due to wear in fuel injection pumps, because the desulfurization process removes substantial amounts of molecules acting as natural lubricants. These have to be substituted by highly efficient lubricity additives (see Section 5.2). The lubricity performance of diesel fuels is defined by a laboratory rig test according to EN ISO 12156-1.

3.2.6. Viscosity

To ensure optimal engine performance the fuel's viscosity at 40 °C has to comply with narrow limits, e.g., in Europe it must be between 2.0 and 4.5 mm^2/s. (EN ISO 3104). Too low a viscosity can lead to wear in the injection pump; too high a viscosity deteriorates injection and mixture formation.

3.2.7. Volatility

The diesel engine is far less sensitive to changes in the fuel volatility than the Otto engine. However, the boiling range of a diesel fuel (EN ISO 3405) influences other properties such as viscosity, flash point, autoignition temperature, cetane number, density, and cold flow performance. Raising the back end temperature, for example, also raises the cloud point; lowering the temperature of the front end also lowers the flash point of the fuel. Generally speaking the variations in volatility of commercial diesel fuels are modest and usually far less significant than the influence of individual engine design features. To reduce exhaust emissions the amount of high boiling fuel components has been limited by lowering the specified 95 % point (temperature for 95 % evaporation) from previously 370 °C to 360 °C. Because of the intercorrelation with the other above mentioned physical properties it is not necessary to specify the light end of the diesel fuel by distillation properties.

3.2.8. Diesel Fuel Stability, Cleanliness, etc.

Safe storage and transportation of diesel fuels, their filterability, injector cleanliness, and compatibility with metals is achieved by meeting a number of specification criteria:

The minimum flash point (EN ISO 2719) of diesel fuel has been set to 55 °C in Europe by law. This limit has been adapted to the safety design elements of diesel fuel tanks which are less rigid than those for gasoline. Contamination of diesel fuel with small proportions of gasoline reduces the flash point below the legal limit and makes storage and transportation unsafe. However, it is legal to blend diesel fuel with gasoline in the vehicle tank to improve the cold flow performance at extremely low temperatures.

Total dirt (EN 12662) and water content (EN ISO 12937) are limited to guarantee acceptable filterability especially at low temperatures when filter elements may additionally be loaded with wax formed from paraffinic fuel components.

Carbon residue (EN ISO 10370) and oxidation stability (EN ISO 12205, ASTM D 2274) give an indication of possible deposit formation in the fuel system. Deposit formation is also controlled by addition of additives (see Section 5.2.2).

Table 3. Summary of effects of diesel fuel properties on emissions in light duty vehicles[b] (Source: EPEFE program)

	Change	CO	HC	NO_x	PM[d]

Reduce T 95[e]	370 to 330 °C	− 0	− 0	− 0	− 0

0 = no effect. ± 0 = −2 to +2 %. ▼ or ▲ = 2 – 10 % effect. ▼▼ or ▲▲ = 10 – 20 % effect. ▼▼▼ or ▲▲▲ = > 20 %. ? = insufficient information.
[b] Effects are not necessarily additive.
[c] Insufficient data is available to reliably separate the influence of these parameters.
[d] PM = particulate matter.
[e] T 95 = temperature for 95 % evaporation.

The anticorrosion properties are specified by means of the copper corrosion test (EN ISO 2160). Again they can be improved by specific additives (see Section 5.2.6).

3.2.9. Diesel Fuel Effects on Exhaust Emissions

The performance of a diesel engine is less sensitive to changes in fuel quality than that of the gasoline engine. However, in the diesel engine the fuel effects on emissions are more complex for several reasons: (1) The reduction of undesired exhaust gas constituents was so far achieved mainly during the combustion process and to a lesser extent by aftertreatment; (2) there is a wider range of engine technology in use (however there is now more conformity, i.e., direct injection engines with electronically controlled high pressure injection systems); (3) the diesel fuel composition is more complex than that of gasoline, i.e., because of the higher boiling range the individual molecules are less well defined (e.g., monoaromatics are mainly chemically bonded to long chain paraffins). Also properties and composition are often interlinked, such as aromatics concentration and density.

The effect of fuel properties and composition on exhaust emissions has been studied by oil companies and motor manufacturers – partly in joint programs, e.g., the European Program on Emissions, Fuels and Engine Technologies (EPEFE).

The effect of some fuel parameters, i.e., sulfur and monoaromatics content had been sufficiently documented previously. Sulfur in the fuel increases the emission of sulfur dioxide and of exhaust gas particulates, it has also negative effects on aftertreatment systems. Monoaromatics in the fuel have no measurable effect on exhaust emissions. The effect of other important fuel properties, i.e., density, polyaromatics content, cetane number, and final boiling point has been studied in the EPEFE program. The results of this investigation are summarized in Tables 3 and 4 [20].

For overall reduction of unwanted exhaust gas components it was decided to tighten the specification of diesel fuels in two steps in the years 2000 and 2005, (see also Chap. 6) by increasing the cetane number, reducing the maxi-

Table 5. Important properties of various gasoline components (approximate values) [3]

mum sulfur content, the final boiling point and the density and by introducing a maximum limit for polyaromatics.

3.2.10. Performance Additives

To ensure optimum operation of the car or truck, high-quality diesel fuels contain a variety of special additives which ensure maximum cleanliness of the engine (detergents), minimize the foaming of the diesel during fueling processes (antifoaming additives), prevent corrosion (corrosion inhibitors), improve lubricity (lubricity improver) and improve the cold flow performance (flow improver, wax antisettling additives). Also ignition improvers may be used (see Section 5.2).

4. Fuel Components

The minimum requirements for fuel quality are defined in standards or specifications (see Chap. 6) to guarantee trouble-free engine operation and acceptable exhaust emissions. These requirements must be fulfilled in refineries by best use of the available product streams [26]. The blending of gasoline and diesel fuels therefore requests the careful selection of suitable refinery components, with sometimes very different physical and chemical properties in different refineries (see also → Oil Refining) or as a result of crude oil properties. More stringent requirements for the improvement of exhaust emissions post catalyst bring with them more and more intense refining processes such as, e.g., desulfurization.

4.1. Gasoline Components

The most important criteria that determine the suitability of gasoline components are the octane numbers (RON and MON), volatility (boiling properties and vapor pressure) and more recently chemical composition (aromatics, absence of benzene, olefins and sulfur) (Table 5). Gasoline fuels consist of hundreds of individual

Table 6. Approximate composition of various fuel components (in volume percent)

Component	Paraffins	Olefins	Aromatics
Straight-run gasoline	94	1	5
Butane	100		
Pyrolysis gasoline*	ca. 20	ca. 10	ca. 70
Light coker gasoline	ca. 57	ca. 40	ca. 3
Light catalytically cracked gasoline	61	26	13
Heavy catalytically cracked gasoline	29	19	52
Light hydrocracked gasoline	100	0	0
FR reformate (94)**	45		55
FR reformate (99)**	38		62

Alkylate	100		
Polymer gasoline	5	90	5

* Reflux from petrochemical plants; after partial hydrogenation.
** For abbreviations, see Table 5.

chemical substances belonging mainly to one of the following three groups: aromatics, paraffins, and olefins (Table 6).

Oil refineries normally have extremely interdependent structures (→ Oil Refining) and, accordingly, many different fuel components are produced. The properties of fuel components, however, depend not only on the type of conversion process and the feed used, but also substantially on the mode of operation of the process.

4.1.1. Straight-Run Gasoline

This gasoline component is obtained by distillation and is therefore easiest to produce and also longest in use. The composition of straight-run gasoline depends on the type of crude oil used (frequently high paraffin content). The octane quality is usually low.

In the past, when highly leaded fuels were used, straight-run gasoline was a primary component of fuel. Currently (ca. 2000), the proportion of straight-run gasoline in motor fuel is generally very low (0 – 20 %).

Butane also belongs to the straight-run products but it has a high octane level. It is added to gasoline, besides being used as liquefied petroleum gas (→ Liquefied Petroleum Gas). Because of its high vapor pressure, butane is good for engine cold-start. On the other hand, too high a vapor pressure can lead to hot-fuel handling problems (warm start problems, stumbling engine, vapor lock) and increased evaporative hydrocarbon emissions [27]. Thus, addition of butane is limited by the vapor pressure specifications.

The yield of straight-run products supplied naturally by crude petroleum cannot meet the high demand for gasoline either qualitatively or quantitatively. Thus, high-boiling components of crude petroleum are cracked either thermally or catalytically into lower boiling products that can be used in gasoline production.

4.1.2. Thermally Cracked Gasoline

Thermally cracked gasoline is often used in the form of *pyrolysis gasoline.* It is obtained in particular as a byproduct from steam crackers (→ Ethylene) in petrochemical plants and has a high content of olefins and aromatics (with good octane quality). BTX (benzene, toluene, xylene) aromatics are frequently extracted from pyrolysis gasoline as valuable raw materials for chemical processes, so only the residues from petrochemical plants are sometimes used in gasoline production [28].

Variants of thermal cracking are *visbreaking* and *coking* (→ Oil Refining, Chap. 3.6.4.1). The relatively small quantities of gasoline obtained (visbreaker gasoline and coker gasoline) are olefin-rich and have a low octane quality.

4.1.3. Catalytically Cracked Gasoline

Catalytically cracked gasoline is more important for gasoline production. It has a high concentration of olefins and has to be desulfurized to be suitable for modern gasolines. Catalytically cracked gasoline is usually separated into high-boiling and low-boiling fractions, which have different applications. The octane quality (especially the MON) of catalytically cracked gasoline is usually sufficient only for regular gasoline. In order to meet the legally defined olefin specification of gasolines the amount which can be used in gasoline production is limited. The high olefin content of these fuel components also requires special precautions to be taken against polymerization and oxidation during their use (see Section 5.1.3).

Another variant of catalytic cracking is *hydrocracking*, a process in which hydrogen is added. The hydrocracked gasoline produced by this process contains practically no unsaturated components and consists principally of iso- and cycloparaffins. Hydrocracked gasoline has a high MON, a moderate RON, relatively low density, and high volatility [29].

4.1.4. Catalytic Reformate (Platformate) (→ Oil Refining, Chap. 3.4)

One of the most important motor gasoline component is catalytic reformate, sometimes referred to as platformate. Reformate has an exceptionally high aromatic content and a very high octane quality. It is obtained by reforming (isomerization and dehydrogenation reactions) from paraffin-rich straight-run gasoline with a low octane quality [30]. The properties of the reformate essentially depend on the mode of operation in the reforming process [31]. When very high octane numbers are achieved, the aromatics content and the density increase, but at the same time the yield and volatility decrease. Because of its high octane quality, reformate is the backbone for the production of lead-free premium fuels. The restrictions of benzene and aromatic content in gasoline fuels limit the use of these components and also requires specific treatment of the reformer feed and/or the reformed product to remove the benzene from this stream (mainly distillation and hydrogenation techniques).

4.1.5. Isomerate (→ Oil Refining, Chap. 3.7.3)

The demand for volatile gasoline components with sufficient octane quality cannot be met by, e.g., unrefined straight-run gasoline [32]. For this reason, from the 1970s onward the low-octane straight-run gasoline was increasingly converted into the higher octane isomerate (mainly isoparaffins). Because it is free from aromatics isomerate is becoming increasingly attractive for environmental reasons.

4.1.6. Alkylate (→ Oil Refining, Chap. 3.7.1)

Another attractive fuel component consisting mainly of isoparaffins is alkylate, which is moderately high in octane quality (especially with regard to the MON), however, less suitable to formulate higher octane premium fuels like Super Plus (minimum RON 98). Alkylate is obtained by the reaction of isobutane with olefins and can only be produced in limited capacity because of the low availability of isobutane.

Since the introduction of mandatory maximum aromatic levels in gasolines alkylate has become one of the most important components for the production of premium fuels. Alkylate is the main component in aviation gasoline (Avgas).

4.1.7. Polymer Gasoline (→ Oil Refining, Chap. 3.7.2)

A less common gasoline component is polymer gasoline, obtained by oligomerization of propene or butenes produced in cracking plants. It consists primarily of $C_6 - C_{12}$ olefins.

4.1.8. Oxygenates

High octane quality of unleaded gasoline can be obtained more easily by the addition of oxygen-containing fuel components [33, 34]. In particular, the addition of methyl *tert*-butyl ether (MTBE) (→ Methyl Tert-Butyl Ether) has proved to be very useful for maintaining the octane quality of unleaded high octane fuels, even

more since the introduction of maximum aromatic levels of 42 vol % (2000) and 35 vol % (2005). Besides its high octane quality MTBE is a very clean burning gasoline component.

Furthermore, methanol, ethanol produced from biomass, or higher alcohols can be used in low concentrations.

4.2. Diesel Fuel Components

The self-igniting diesel combustion process requires molecules with different structures than used in gasoline, i.e., in contrast to gasoline diesel fuel components must decompose easily at high temperature and pressure. Normal *n*-paraffins are for that reason ideal diesel fuel constituents, in contrast to olefins and aromatics. However, because of the higher boiling range of diesel fuel, the hydrocarbon molecules often consist of a combination of different structural moieties (e.g., an aromatic ring with a long paraffinic or olefinic side chain). The main characteristics determined by the composition of the diesel fuel are its ignition performance, cold flow properties, volumetric calorific value, and density. The latter can affect the air – fuel ratio and therefore influences particulate emissions (smoking tendency) under maximum torque conditions.

None of the classes of substances present in diesel fuel fulfills all the criteria equally well; for example, *n*-paraffins, which have a very good ignition performance and low smoking tendency, show poor low-temperature behavior and have a low calorific value (Table 7). However the combination of, e.g., paraffinic and aromatic substructures in the molecules can reduce cold flow problems without significantly impairing the combustion properties.

The diesel engine can also theoretically be run on lower and higher boiling hydrocarbons. Marine diesel engines for example use higher boiling residual fuels (→ Heating Oil, Chap. 2). The particular value of the automotive diesel engine lies, however, in its ability to utilize economically the middle distillates in the distillation range 150 – 360 °C. Accordingly, the diesel fuel components produced in refineries must correspond to the aforementioned requirements as far as possible.

4.2.1. Straight-Run Middle Distillate

Straight-run middle distillate (distillate gas oil) represents a valuable diesel fuel component because of its usually high cetane number (see Fig. 4). The quality of straight-run middle distillate nevertheless depends strongly on the quality of crude petroleum used. In many cases, distillate gas oil has a relatively high paraffin and low aromatic content.

Figure 4. Typical properties of gas-oil components
a) Synthetic middle distillate; b) Straight-run gas oil; c) Hydrocracked gas oil; d) Thermally cracked gas oil; e) Syncrude gas oil; f) Coker gas oil; g) Light catalytically cracked cycle oil

Although middle distillates can be used for the diesel engine without further processing (apart from desulfurization), other diesel fuel components are also employed. The following

Table 7. Properties of various hydrocarbon groups with regard to their suitability as diesel fuels

	Ignition quality	Cold flow properties	Volumetric calorific value	Density	Smoking tendency
n-Paraffins	good	poor	low	low	low
Isoparaffins	low	good	low	low	low
Olefins	low	good	low	low	moderate
Naphthenes	moderate	good	moderate	moderate	moderate
Aromatics	poor	moderate	high	high	high

Table 8. Properties of diesel fuel components

Process	Component	Composition	
		Before treatment	After treatment
Distillation	distillate gas oil (straight run)		content of aromatics: medium; olefins: very low; paraffins: high
Thermal cracking	thermocracked gas oil	content of aromatics: low; olefins: medium; paraffins: high	content of aromatics: low; olefins: none; paraffins: high
Catalytic cracking	catalytically cracked gas oil	content of aromatics: high; olefins: low; paraffins: low	content of aromatics: high; olefins: none; paraffins: low
Hydrocracking	hydrocracked gas oil		content of aromatics: very low; olefins: none; paraffins: very high
SMDS synthesis	synthetic gas oil		content of aromatics: none; olefins: none; paraffins: very high
Distillation or hydrocracking	kerosene		content of aromatics: low; olefins: none; paraffins: very high

reasons are decisive: (1) the natural middle distillate fraction in crude petroleum is generally not sufficient to meet the demand for middle distillate; (2) unwanted heavy components in crudes are present in excess and are, therefore, converted into lighter products; (3) the refinery structures also provide a certain "compulsory fraction" of middle distillates from conversion processes; and (4) particular quality requirements can also make the production of special diesel fuel components necessary.

4.2.2. Thermally Cracked Gas Oil

Thermally cracked gas oil originates from either the visbreaking or the coking process and tends to have a lower cetane number and higher density than distillate gas oil (Table 8). Thermally cracked gas oil usually goes through a subsequent hydrogenation step because of the formation of unstable olefinic components during the cracking process. After hydrogenation, it represents a usable diesel fuel component.

4.2.3. Catalytically Cracked Gas Oil

Catalytically cracked gas oil is generally characterized by a very low cetane number and high density. Because of its instability, catalytically cracked gas oil must normally be hydrogenated [35]. Because of the poor ignition performance resulting from the high aromatic content and the high smoking tendency, it can be added to diesel fuel only in limited quantities.

4.2.4. Hydrocracked Gas Oil

Hydrocracked gas oil is a very valuable diesel fuel component. Because of its very high paraffins content, the ignition performance is good and the smoking tendency low.

4.2.5. Kerosene

Improved cold flow properties of diesel fuel can be achieved by the addition of kerosene. Because kerosene is predominantly used as jet fuel and, therefore, expensive and in short supply, its addition is limited mainly to meet the requirements of low temperature climatic conditions. The density, calorific value, and viscosity of kerosene are in most cases, however, much lower than those of other diesel fuel components and therefore its use is limited anyway. The low density and low calorific value would lead to decreased engine power and increased volumetric fuel consumption. The low viscosity would require additives to avoid wear in the injection pump because of poor lubricity.

4.2.6. Synthetic Diesel Fuel

Diesel fuel can also be obtained from fossil energy sources other than crude petroleum. Dur-

ing World War II diesel fuel was produced from coal by the Fischer –Tropsch process in Germany. This synthetic fuel (*kogasin*) had a range of outstanding properties: cetane number ca. 100, almost sulfur-free composition, low density, and high gravimetric calorific value. This synthetic diesel fuel component was used principally for enhancing low-value coal tar oil. Synthetic diesel fuel is produced in small quantities by the Shell Middle Distillate Synthesis (SMDS) process in Malaysia from natural gas [36]. The process includes the following steps:

1) Steam reforming of natural gas (conversion to synthesis gas),
2) Buildup of long-chain *n*-paraffins (Fischer – Tropsch synthesis),
3) Isomerization to isoparaffins
4) Distillative separation into kerosene and diesel fraction

The product was initially used mainly for improvement of the poor quality of the straight-run middle distillate otherwise available in Malaysia. The middle distillate produced by the SMDS process results in lower exhaust emission in diesel engines because it has a high cetane number (> 60). To meet increasing requirements for diesel fuel quality of modern low emission engines synthetic middle distillates are meanwhile used as components in top-quality diesel fuels.

A process is currently under development is to convert biomass to gas on a commercial scale with subsequent use of the SMDS process.

5. Fuel Additives

By the generally accepted definition only agents that are added to fuels in a concentration of $<$ 1 % should be described as "additives." For substances present in higher concentration, the term "fuel components" is more appropriate.

Fuels are treated with additives for various reasons: in the past the addition of octane enhancers to gasolines enabled the production of high octane grades. Nowadays the use of cetane improvers offers the possibility of upgrading a base fuel very economically compared with refinery measures.

Performance additives, on the other hand, which are added to modern high quality fuels, improve the behavior of a base fuel in operation, and offer technical advantages that often cannot be achieved by measures taken in the refinery [37]. In many cases, these types of additives offer the only possibility of guaranteeing trouble-free engine performance over a longer running period. Finally, treatment of fuels with additives is a major route to achieve product differentiation and trademarked quality.

Thus it is not surprising that in Western Europe further increase in the use of additives is generally anticipated [38] with the exception of the alkyllead compounds which due to their incompatibility with exhaust catalysts and their toxicity have been phased out as of January 1, 2000 in the EU. A derogation of two years for the lead phase out was granted to Spain, Italy, and Greece by the EU commission. Lead phase out is a general trend worldwide, except for developing countries with low car population.

5.1. Gasoline Additives

The treatment of gasoline with additives is almost as old as the fuel itself [39]. At first (around 1900), the search for so-called brisance-increasing additives was predominant (Fig. 5). In 1918, treatment with certain additives was recognized to allow an increase of compression ratio without dangerous knocking. An increase in the octane number became the major aim for decades in additive technology. Systematic research into additives that could positively influence many aspects of engine behavior began around 1950 on a wider scale. Since ca. 1970, conventional, ash-forming antiknock additives became increasingly less important for environmental reasons. Nowadays additive development is driven by environmental specifications as well as demanding new technologies like direct injected gasoline cars.

5.1.1. Corrosion Inhibitors

Water is almost always present in traces and can ingress into the fuel during processing, transfer, and storage by condensation. Moreover alcohols, when present in the fuel, can also lead to corrosion problems either by themselves or because of their water-solubility. Corrosion must

Figure 5. Historical development of gasoline additives

be inhibited not only to avoid damage of the tank or the fuel system but also because fine rust particulates can block fuel filters and injectors.

The effect of corrosion inhibitors is based on their ability to cover a metal surface with a monomolecular layer of inhibitor molecules and thus protect it from contact with corrosive components [40]. The structure of the corrosion inhibitors corresponds to this requirement: a polar end of the molecule (e.g., a carboxylate, ester, or amine group) is attached to the metal surface; while a nonpolar, high molecular mass alkyl chain at the other end of the molecule extends into the hydrocarbon phase (Fig. 6). An oily covering layer is thus formed that effectively repels water.

High alcohol contents in fuel (e.g., gasohol in Brazil) are a problem because alcohols, in addition to their own corrosiveness, can also dissolve the protective film. Apart from these cases, which require exceptionally high concentrations (e.g., 100 ppm) of corrosion inhibitors, 10 – 20 ppm, is generally sufficient for effective corrosion protection.

Figure 6. Mode of action of corrosion inhibitors

The efficiency of corrosion inhibitors can be tested in the corrosion test according to DIN 51585, ASTM D 665, in which gasoline – water mixtures are allowed to react with steel test objects.

Examples of suppliers are BASF (Kerokorr additives), Octel (DCI series), Lubrizol (LZ series), Bayer AG (RC additives), Infineum, Nalco/Exxon, Baker/Petrolite (Tolad) Betz-

Dearborn, Apollo Technologies (PRI), UOP (Unicor), Ethyl (Hitec), and Champion Technologies (RPS).

5.1.2. Detergents

In Otto engines, high molecular mass organic deposits can be formed in various sites in the fuelling and inlet and mixing systems. These deposits can lead to considerable problems in engine operation. Deposits on the *carburetor* and *injectors* prevent the formation of an optimal fuel – air mixture and cause increased fuel consumption and poor exhaust gas emissions [41 – 43]. In extreme cases the engine can even stall. Severe deposit formation on the *inlet manifolds* and *valves* causes, in addition to increased fuel consumption and deterioration in exhaust emissions, a decrease in power [44 – 47]. Sometimes even mechanical engine damage can occur.

The formation of deposits is caused by several factors [48 – 51]: Fuel components with high olefin or heteroatom content (which also have a marked tendency toward gum formation) are relatively prone to deposit formation. This is also true for fuels with very high final boiling points. Engine oil, which enters the inlet system via the valve stem guides, also contributes to deposit formation. Finally, combustion gases play a role in deposit buildup. These gases get into the inlet system either with the recirculated blowby gases from the crankcase or directly from the combustion chamber because of valve overlap. The multiplicity of factors contributing to deposit buildup shows that the problem cannot be solved by individual improvements in single areas but only by the addition of detergents with extensive effectiveness.

Detergents for Carburetor and Injector Cleanliness. Detergent additives were first used in the 1950s to maintain carburetor cleanliness ("keep clean effect"). Later, detergent additives were developed which removed deposits already present in the carburetor ("cleanup effect"). First-generation detergents were specially designed to work in the relatively cold region of the carburetor. These detergents include alkylamines, alkyl phosphates, alkyl-substituted succinimides, imidazolines, and oleylamides, which were added to the fuel in concentrations of 50 – 100 ppm. These compounds are also suitable, in principle, for keeping injectors clean, although concentrations of 150 – 300 ppm are then required [52].

To assess the efficiency of a carburetor detergent additive, the CEC developed a test cycle with a Renault 5 engine [53].

Detergents for Inlet Valve Cleanliness. From the mid-1970s, the search for decreasing fuel consumption and increased power led to leaner fuel – air mixtures and temperature increases in the inlet system. This created several problems that could not be overcome by the first-generation detergent additives, because these were effective only in the low-temperature range. In individual cases the carburetor detergents caused even higher deposit accumulation on the inlet valves due to decomposition.

The development of second-generation detergent additives made it also possible to keep the hot inlet valve clean [47, 54 – 56]. Long-chain, high molecular mass alkyl compounds (molecular mass around 500 – 1500 g/mol) with a polar end group, are very effective. The mechanism is analogous to that of corrosion inhibitors described in Section 5.1.1. Effective, modern detergent additives are based on polyisobuteneamine, polyisobuteneamide/succinimide, or polyetheramine technology. To meet most stringent environmental legislation these additives have to be produced halogen-free. These detergents, except for the polyetheramines, are normally used in combination with very thermally stable carrier oils that keep the surface of the valve lubricated and ensure continuous flowing off of deposit particles. To keep inlet valves clean relatively high concentrations of detergent (300 – 400 ppm) and carrier oil (300 – 400 ppm) are used. Depending on the polar end group modern detergents provide both keep-clean as well as cleanup performance.

A number of tests have been developed to assess the detergency performance of these gasoline additives: the Mercedes Benz M102E test was developed in Europe by CEC [57, 58].

Examples of suppliers are BASF (Keropur multipurpose additives), Infineum (Vectron), Ethyl (Hitec), Octel (OGP), Oronite (OGA series), and Lubrizol (ADX).

5.1.3. Antioxidants (→ Antioxidants)

As early as 1930 the aging of gasoline was known to be inhibited considerably by antioxidants (oxidation inhibitors). Nevertheless, antioxidants achieved importance only after World War II, when olefin-rich fuel components from cracking processes were increasingly used (→ Oil Refining). Olefins, in particular conjugated dienes, undergo liquid-phase free-radical chain reactions relatively easily at low temperature, which finally lead to the formation of highly polymeric residues, the so-called gum [59]. Other potentially gum-forming components are aromatics and the nitrogen and sulfur compounds present at trace levels. The efficiency of antioxidants is based on their capability to interfere with the mechanism of gum formation. In this mechanism, the initiating step is formation of a radical ($R^1-H \rightarrow R^1\cdot$); in the second step, hydroperoxides are formed by reaction with dissolved oxygen from the air and the chain reaction is started (Eqs. 1 and 2):

$$R^1\cdot + O_2 \rightarrow R^1-O-O\cdot \quad (1)$$

$$R^1-O-O\cdot + R^2H \rightarrow R-O-OH + R^2\cdot \quad (2)$$

Gum-forming reactions continue until the chain reaction is terminated by the coupling of two radicals (Eqs. 3 and 4). The chain termination reaction can also be taken over by an antioxidant (AH), which leads to the formation of an inactive radical A· that is not able to continue the chain reaction (Eq. 5):

$$R^1\cdot + R^2\cdot \rightarrow R^1-R^2 \quad (3)$$

$$R^1-O-O\cdot + R^2\cdot \rightarrow R^1-O-O-R^2 \quad (4)$$

$$R^1-O-O. + AH \rightarrow R^1-O-O-H + A \quad (5)$$

The aging of gasoline must be inhibited not only because of gum formation, which (1) blocks carburetors and injectors, filters in engines or dispenser pumps; and (2) can lead to dirt accumulation in the inlet system. An additional function of the antioxidant used to be the stabilization of tetraethyllead.

The gum content of gasoline fuels is measured according to EN ISO 6246, ASTM D 381, giving the washed gum evaporation residue. The residue has to be washed with *n*-hexane to remove detergent additives and carrier oils used in high performance fuels.

The induction period (EN ISO 7536) is a laboratory test to measure the storage stability of gasolines. Most antioxidants belong to one of the following two classes of substance.

para-Phenylenediamines have the general formula $R^1-NH-C_6H_4-NH-R^2$, in which R^1 and R^2 can be *sec*-butyl-, isopropyl-, 1,4-dimethylpentyl-, or 1-methylheptyl-. *para*-Phenylenediamines are very effective at concentrations of 5 – 20 ppm, particularly for gasolines with high olefin content. Their basicity, however, makes them susceptible to reaction with acidic impurities or fuel components. On the other hand, phenylenediamines offer the advantage of catalyzing the oxidation of mercaptans (which have foul odors even when present in trace amounts) to odorless disulfides.

Hindered Alkylphenols. Alkylphenols are optimally efficient if their hydroxyl group is sterically hindered by alkyl groups in positions 2 and 6, e.g., as in 2,6-di-*tert*-butylphenol.

Alkylphenols are particularly suitable for olefin contents $< 10\,\%$. Because of steric hindrance, the acidity of the hydroxyl group is lowered to such a degree that the danger of side effects is low. To achieve the same efficiency as phenylenediamines, higher concentrations (5 – 100 ppm) are necessary. Because of their positive synergism, mixtures of phenylenediamines and alkylphenols are also used sometimes [60].

Examples of suppliers are BASF (Kerobit additives), Octel (AO), and Ciba (Irganox).

5.1.4. Metal Deactivators

The aging (oxidation) of gasoline can be accelerated considerably by traces of metals that get into the fuel during transfer. Mercaptans, phenols, and alcohols increase the solubility of metals in fuel. Copper has the highest catalytic activity, accelerating the oxidation of fuel considerably at concentrations as low as 0.01 mg/L.

The function of metal deactivators is based on the fact that they form stable chelate complexes with dissolved metal atoms so that the metal loses its undesirable catalytic activity

[40]. The addition of *N,N′*-disalicylidene-1,2-propanediamine is particularly effective,

and copper is complexed as follows:

Examples of suppliers are BASF (Keromet additives) and Octel (DMD).

5.1.5. Anti-Icing Additives

The problem of carburetor icing has virtually disappeared because of the introduction of multipoint fuel injection systems which are practically immune to icing.

During the evaporation of fuel in the carburetor or in single point injection systems, heat is absorbed from the surroundings so that even at ambient temperatures > 0 °C, temperatures below 0 °C can occur and lead to freezing of the air moisture there. Besides its temperature, the relative humidity of the air is an important factor for the formation of icing (Fig. 7) [54].

Figure 7. Effect of relative air humidity and air temperature on carburetor icing [54]
a) Severe icing; b) Icing; c) No icing

Carburetor icing was particularly noticeable during idling (engine stalling because of ice formation) or constant speed driving making itself noticeable by engine power loss, high fuel consumption, unfavorable exhaust gas emissions, and finally, engine stalling. To avoid carburetor icing, two different types of additives were used: (1) surfactants and (2) freezing point depressants (→ Antifreezes).

Surface-Active Substances. Surfactants produce protective films over the metal surface so that ice is prevented from sticking to it. Examples of surface-active compounds are amines, diamines, amides, or glycol esters of fatty acids, which are effective at 10 – 60 ppm. Other surface-active substances added to fuels, such as detergents, act as anti-icings in addition.

Freezing Point Depressants. Effective freezing point depressants include alcohols, glycols, dimethylformamide, and other water-soluble polar substances. Depending on the type used they were added in concentrations of 0.02 – 2 vol %.

5.1.6. Additives for Combating Combustion Chamber Deposits

Mainly when leaded gasolines were used considerable quantities of lead compounds, but also carbon, and engine oil components could deposit in the combustion chamber and on the spark plugs [61 – 64]. This could lead to knocking combustion and to spark plug fouling problems.

Organophosphorus and organoboron compounds were therefore added to fuel at an early stage. These additives do not remove the deposits but are at least able to convert them to materials with high glow temperature and low electrical conductivity (*deposit modifiers*). The commercial products contained, for example, tricresyl phosphate, triisopropyl phosphite, borazane, or boric acid esters. These additives are no longer on the market because (1) the phase out of lead compounds reduced the problem and (2) phosphorus compounds are incompatible with catalytic converters because of their tendency toward catalyst poisoning.

Research was devoted to the development of *ash-free* additives, which counteract the buildup of combustion chamber deposits and control any increase in the octane number requirement of the engine [*octane requirement increase control*

(ORIC) additives]. These additives have shown some positive effects in test engines. However their effect under actual road conditions seems to be limited. Reduced engine oil consumption, precise fuel metering to obtain stoichiometric air-fuel ratios, the shape of modern combustion chambers and of course the use of unleaded gasoline have reduced the problem of combustion chamber deposit formation. Specific additives to reduce these deposits are therefore not in general use.

5.1.7. Valve Seat Recession Protection Additives

Some older cars with "soft valve seats" (e.g., cast iron) relied on leaded gasoline, since lead compounds inhibited corrosion and wear of the valve seats. Unleaded gasoline for older cars can be provided with organic potassium or sodium compounds as lead replacement. These can be added to the finished fuel by the end consumer using a bottle solution. However, valve seat recession occurs predominantly under high-duty (motorway) operation. As vintage cars with soft valve seats are normally not operated under these conditions it is generally not necessary to use these additives.

5.1.8. Antiknock Agents (→ Octane Enhancers)

The most important antiknock additives were alkyllead compounds, i.e., tetraethyllead and tetramethyllead. As pointed out the use of these additives was discontinued because of their poisoning effects on the exhaust-gas aftertreatment systems and their toxicity. Other metal-based antiknock additives have either similar unwanted side effects or limited activity. Organic antiknock additives are less effective than ash forming products. Best known are nitrogen-containing aniline derivatives. None of these antiknock additives is used commercially on a larger scale. Instead oxygen-containing blending components, mainly ethers (→ Octane Enhancers; → Methyl Tert-Butyl Ether) are used to increase the octane quality of unleaded gasolines.

5.1.9. Dehazers and Antistatic Additives

Dehazers and antistatic additives are rarely used in gasoline. They are similar to the corresponding types of additives in diesel fuel (see Sections 5.2.7 and 5.2.9).

5.2. Additives for Diesel Fuel

Apart from a few exceptions treatment of diesel fuel with additives was introduced much later than that of gasoline. Several reasons existed for the introduction of additives: (1) a significant progress in diesel engine technology occurred from about the mid-1970s onward which led to a greater market share of diesel engines in passenger cars; (2) fleet operators and car owners required improved reliability and comfort; (3) more stringent emission standards required improved diesel quality.

5.2.1. Ignition Improvers (Cetane Improvers)

The cetane number (see Section 3.2) is a measure of the ignition quality of a diesel fuel. Because a range of aspects essential to the operation of diesel engines are also connected with the cetane number (cold-start properties, particulate, e.g., white and black smoke emission, noise emission, fuel consumption, engine durability), the increase in cetane number by additives is a valuable means of improving diesel fuel quality [65].

The effect that can be achieved by the use of ignition improvers depends on the base diesel fuel. Unfortunately, base fuels with high natural cetane numbers react better to additive treatment than those with lower cetane numbers, for which an increase in the cetane number is more essential (Fig. 8). In view of constantly increasing efforts to reduce exhaust gas emissions, the fact that even small quantities of ignition improvers can improve the exhaust gas quality of the diesel engine is important (Fig. 9) [66, 67].

The effect of ignition improvers is based on their rapid decomposition, with the formation of free radicals that accelerate the chain reaction of diesel fuel combustion. Suitable compounds

are alkyl nitrates, ether nitrates, alkyldiglycol nitrates, and organic peroxides. From a commercial point of view only alkyl nitrates such as 2-ethylhexyl nitrate (EHN) have been successful. With these compounds, the ready cleavage of the $RO-NO_2$ bond leads to radical formation [69].

Examples of suppliers are Octel (CI additives) and Ethyl (Hitec).

Figure 8. Response of different base fuel types to addition of ignition improvers

Figure 9. Improvement of exhaust gas emissions by ignition improvers; average emissions of three passenger cars with pre- and swirl chamber diesel engines [67]

5.2.2. Detergent Additives

Corresponding to the different construction of the diesel engine compared with the Otto engine, the problem of deposit formation occurs in a different form. In diesel engines the injection system is particularly affected, where gum- or carbonaceous deposits are formed on the injectors. This inhibits the ability of the valve needle to move and the formation of a finely dispersed spray of fuel. The mixing system is thus disturbed, and increased emissions (particulates), higher fuel consumption, and lower engine power, result.

A range of substances are suitable as detergents in diesel engines: amines, imidazolines, amides, succinimides, polyalkyl succinimides or amines, and polyetheramines [70, 71]. The following mechanism of action has been proposed: the surface activity of the polar groups ensures the formation of a protective film, whereas the dispersing effect of the polymeric chain prevents agglomeration and deposit formation by smaller particles. In this way a "keep clean effect" can be achieved; however, for already dirty nozzles, a solubilization of formed deposits material is also necessary. The addition of detergents offers other advantages for diesel fuel, such as better storage stability and a certain amount of protection against corrosion [72].

Examples of suppliers are Infineum (Vectron), Octel (OMA), Oronite (ODA series), and Lubrizol.

5.2.3. Cold Flow Additives

Diesel fuel has the unfortunate property that crystallization of high molecular mass *n*-paraffins (waxes) can occur at low ambient temperature. These wax crystals can clog the fuel filter and lead to engine stoppage after a short period of operation. The tendency toward wax separation depends strongly on the composition of the diesel fuel, which is determined mainly by the crude petroleum used and the refinery structure [73]. In principle, the low-temperature behavior of a diesel fuel could be improved by removing the particularly critical *n*-paraffins. However, this would be unacceptable not only because of the high costs, but also because *n*-paraffins are very valuable diesel fuel components due to their good ignition performance and low smoking tendency [74].

Before the development of highly effective additives for improving low-temperature properties, owners of diesel vehicles were frequently forced to add up to 30 % regular gasoline to

Figure 10. Mode of action of flow improvers [79]
MDFI = Middle distillate flow improvers

diesel fuel, risking engine damage and increased exhaust emissions.

To assess the low-temperature behavior of diesel fuel the following two laboratory test procedures are used:

1) **Determination of the Cloud Point** (EN 23015, ASTM D 2500). The cloud point is the temperature at which diesel fuel begins to become turbid at a defined cooling rate because of the separation of small wax crystals. The cloud point is especially important for the evaluation of refinery components in order to determine type and amount of cold flow additive that has to be added to the components. The cloud point does not define the operability of the final, additivated diesel fuel.
2) **Determination of the Cold Filter Plugging Point (CFPP)** (EN 116) [75, 76]. The CFPP is the limiting temperature at which, under defined conditions, a diesel fuel sample can no longer pass through a metal sieve within a specified length of time. Generally speaking the CFPP gives a reliable indication of the operability limit expected for a diesel fuel in modern vehicles. Since the development of wax antisettling additives, which drastically lower the CFPP, the operability of critical older vehicles (e.g., without heating of the fuel system) is not as low as suggested by the CFPP result.

Flow Improvers. Flow improver additives improve the cold flow properties of diesel fuels in a cost- effective way. Refineries are given the flexibility to use high cetane quality paraffinic product streams for diesel fuel, kerosene, otherwise necessary for achieving good low-temperature behavior of diesel fuel, for the production of jet fuel.

Flow improvers have been used increasingly since 1973. Their mechanism of action is based on two different effects [77]. First, the additive forms crystallization nuclei on reaching the cloud point, to which the wax crystals become adsorbed. Second, further crystal growth is slowed down by adsorption of the additive on the growing crystal surface. Thus, both the crystal size and the tendency to agglomerate are reduced (Fig. 10). The small crystals thus formed have a considerably lower tendency to block fuel filters because they (1) pass through the filters to some extent, (2) produce a still penetrable layer on the filter, and (3) dissolve again rapidly when the engine is warmed.

Flow improvers are effective only when they have been added to the fuel at temperatures well above the cloud point of the base fuel, i.e., at about + 40 °C, and preferably in the refinery. Addition after crystal formation is not effective [78]. Ash-free polymers are used as flow improvers, in the vast majority of cases ethylene – vinyl acetate (EVA) copolymers. The dosage with which a particular CFPP value can be achieved depends on the base fuel and is normally 50 – 500 ppm (Fig. 11).

Figure 11. Effect of a flow improver on various base diesel fuels [54]
a) Poorest response behavior; b) Normal response behavior; c) Best response behavior

Examples of suppliers are BASF (Keroflux additives), Octel (OFI), Infineum, and Clariant (Dodiflow).

Wax Antisettling Additives (WASA). Wax antisettling additives keep small wax crystals in suspension and thus inhibit the formation of wax layers, which can rapidly lead to filter clogging [25]. This is achieved by their ability to slow the growth of wax crystals, which is even greater than that of flow improvers. According to Stokes' law, small particles have a considerably lower settling rate than large ones. By reducing the size of wax crystals by one-fifth, the sedimentation time can be extended from an hour to a day. Wax antisettling additives have been used since 1986 – generally in combination with flow improvers. Typical concentrations are 100 – 500 ppm. They are usually based on modified ethylene – vinyl acetate copolymers.

Examples of suppliers are BASF (Keroflux ES additives) and Infineum [79].

Cloud Point Depressants. The use of conventional flow improvers to lower the CFPP value generally has hardly any influence on the cloud point. However, polymer additives (based on ethylene – vinyl acetate, unsaturated esters, imides, or olefins) have been developed that permit additional lowering of the cloud point. Their mode of action is based on shifting the thermodynamic equilibrium by irreversibly decreasing the crystallization temperature. This particularly increases the solubility of higher molecular mass *n*-paraffins. With a dosage of 500 ppm the cloud point can be lowered by ca. 3 °C. The market importance of cloud point depressants is considerably smaller than that of flow improvers and wax antisettling additives [73].

5.2.4. Lubricity Additives

The intrinsic, natural lubricity of diesel fuel is reduced during the desulfurization process, because surface active components are destroyed during the hydrogenation. In the case of low and ultra-low sulfur diesel fuels the lubricity of the finished product can be too low, resulting in wear problems in the injection pumps. To ensure safe operation low and ultra-low sulfur diesel fuels have to be additivated with efficient lubricity additives. Examples of surface active substances are fatty acid derivatives which are added in the range of 50 – 200 mg/L.

The lubricity performance of fuels is evaluated in the high frequency reciprocating wear rig (HFRR) laboratory test (ISO 12156–1). A maximum wear (HFRR value) is defined and specified in EN 590.

Examples of suppliers are Octel (OLI), Ethyl (Hitec), Infineum, and Lubrizol (LZ).

5.2.5. Antifoam Additives

When a vehicle tank is filled with diesel fuel, severe foam formation can occur because of intensive mixing with air. This has unpleasant effects: either the time necessary to fill the tank completely is extended or the amount of fuel taken into the tank is considerably lower.

Silicon-containing antifoams, mostly polysiloxanes, have been developed and added to diesel fuel at a concentration of 10 – 50 ppm to avoid excessive foam formation. An effective antifoam additive not only depresses foam formation but also accelerates foam decomposition.

Examples of suppliers are Goldschmidt (Tegopren series), OSI Witco (MR additives), and Dow Corning.

5.2.6. Additives for Increasing Storage Stability – Antioxidants

During the storage of diesel fuel, aging and corrosion effects can occur in a way similar to gasoline (see Sections 5.1.3 and 5.1.4). The aging of diesel fuel also occurs via oxidation and radical polymerization reactions, which first cause darkening and later sediment formation [80]. The problem of unstable diesel fuel has increased particularly since ca. 1970 because higher proportions of diesel fuel components from cracking processes are in use [81]. These components have a higher content of unsaturated hydrocarbons than straight-run middle distillates. Middle distillates from cracking processes are generally subjected to hydrogenation ("hydrotreating"); however, additional treatment with antioxidants is often necessary.

In diesel fuel aging, sulfur- and nitrogen-containing substances can also be responsible for sediment formation to a considerable extent, although they sometimes have an oxidation-inhibiting effect. In addition, a high acidity (caused by carboxylic acids or phenols) accelerates aging catalytically. Sediment formation brought about by aging can clog the fuel filter; gumlike deposits can affect the flow of the fuel in the injection pump and the injectors.

The additives used to inhibit aging are similar to those used for gasoline (see Sections 5.1.3 and 5.1.4), namely sterically hindered phenols and phenylenediamines. Trialkylamines are also very efficient. The additive dosage is usually ca. 50 ppm; however, the efficiency depends on the particular diesel base fuel.

Since dissolved metal ions (especially copper) can also catalyze the aging of diesel fuel, ca. 5 ppm of a *metal deactivator* can be added.

Corrosion inhibitors (see Section 5.1.1), which generally consist of high molecular mass amines when used in diesel fuel, are also effective against aging because of their basicity.

The *detergents additives* added to diesel fuel principally to keep the injection nozzles clean are often effective in preventing diesel fuel aging. Additives for stabilizing diesel fuel are frequently used in the form of a multifunctional mixture at a concentration of ca. 100 ppm.

5.2.7. Dehazers

Through contact with water vapor in refinery processes and possible entry of water during transportation and storage, diesel fuel often becomes cloudy due to the presence of finely dispersed water droplets. Since such a cloudy, water-containing fuel would lead to considerable operational problems, the water droplets must have separated before the fuel is distributed. Especially in diesel fuels rich in aromatics, water separation may take a long time so that large tank capacities are necessary. The settling of water can be accelerated considerably by the addition of dehazers. These additives mainly lower the surface tension between water droplets, so that agglomeration to form larger, more rapidly sinking drops is achieved. Quaternary ammonium salts in a concentration of 5 – 50 ppm are effective dehazers.

Examples of suppliers are Rechem (ER and EXP additives), Petrolite (Tolad additives), and Nalco (Nalco).

5.2.8. Biocides (→ Biocides)

As explained in Section 5.2.7, the contact of diesel fuel with water cannot be ruled out totally.

In some cases, water layers are formed at the bottom of the storage tank due to insufficient house keeping. At the interface between water and the diesel fuel, conditions are provided that allow the growth of microorganisms such as bacteria, yeast, and fungi. Infestation with microorganisms leads, on the one hand, to sediment formation which increases the danger of filter blocking. On the other hand, sulfate-reducing bacteria create a corrosive atmosphere that produces rust particles and can finally lead to tank destruction [82]. Through the addition of biocides, microbial infestation can be prevented or already affected tanks can be disinfected.

Microorganisms can develop resistance to biocides under certain circumstances, so biocides should be used only sparingly for specific purposes. Generally careful cleaning of the affected storage tank and consequent removal of water from the tank solve the problem.

A whole range of substances can act as biocides: formaldehyde derivatives, isothiazolones, triazines, *N,N*-methylenebis(5-methyloxazolidine), and boric acid derivatives.

Biocides are usually applied in a range of 50 – 400 ppm.

Biocides are supplied, e.g., by Schülke & Mayr, Norderstedt, Germany.

5.2.9. Antistatic Additives

When hydrocarbons are pumped rapidly, a buildup of static electricity can occur which, on discharge, may lead to fuel vapor ignition. In comparison to kerosene, this danger is relatively small for diesel fuel because of its lower volatility and its content of polar components that lead to increased conductivity. However, the use of small quantities of antistatic additives (up to 5 ppm) which, for example, contain calcium compounds is sometimes advisable where, very high pumping rates (e.g., at refineries, transfer, or truck refueling) can lead to the danger of static charge buildup. Electrical conductivity can be determined by means of a testing method ASTM D 2624, developed for jet fuel.

Antistatic additives are supplied, e.g., by Octel (Stadis).

5.2.10. Reodorants

The odor of diesel fuel is often regarded to be unpleasant, with the result that people can reject diesel engines as "dirty". If the skin or clothes are contaminated with diesel fuel, the unpleasant odor can remain for a long time because of its low volatility.

The unpleasant smell is caused particularly by certain sulfur-containing and unsaturated components. Desulfurization with hydrogen removes most of the unpleasant smelling ingredients. Modern low-sulfur fuels have generally a neutral smell so that specific reodorants are no longer required.

Reodorants are based mostly on nature-identical substances that are toxicologically harmless, such as vanillin or terpenes. They usually work by blocking the olfactory nerves and can be added in concentrations of 30 – 100 ppm.

Examples of suppliers are Haarmann & Reimer (Kompensols) and Bush Boake Allen (LG additives).

6. Fuel Standardization and Testing

The engine performance strongly depends on the physical and chemical properties of a fuel (see Chap. 3). To guarantee adequate fuel quality for a broad range of engine requirements, minimum specifications must be met, which are defined, for example, in *Europe* in EN 228 (for gasoline) and EN 590 (for diesel) (Tables 9 and 10).

Table 10. European standard for diesel fuel; extract from EN 590

** mandatory limits vary depending on climatic conditions, figures shown are valid for central European climate.
*** The specification of 10 mg/kg supports the introduction of "sulfur free" Diesel fuels.

In these specifications the great climatic differences within Europe (Sweden – Portugal, for example) are taken into account be defining appropriate limits for, e.g., volatility of gasoline and cold-flow performance of diesel fuels for each country.

The ASTM testing methods used in the *United States* are similar to the corresponding European (EN, ISO) methods. For all testing procedures a variation in measured values is unavoidable, and determination of a "true value" is

impossible. The terms "true value", repeatability, and reproducibility are precisely defined in EN ISO 4259.

The EN standards for gasoline and diesel fuel are mandatory. The quality of the fuels and their conformity with standards is, for example, tested on a random basis by the appropriate authorities in the Federal Republic of Germany and is followed up by court in the case of an offense. This is all the more important because not conforming to standards can cause damage to engines and provide economic advantages for disreputable suppliers.

7. Storage and Transportation

To transport fuels from the refinery to a vehicle tank a sophisticated infrastructure is necessary.

Storage. In the refinery or in gasoline depots, fuels that are ready for use are first placed in cylindrical, generally steel tanks for intermediate storage. To store volatile gasoline fixed roof tanks with *internal floating roofs* are generally used. The roof, which is sealed against the wall of the tank, can rise and fall with the liquid level. To avoid hydrocarbon emissions the tanks breathe into a sealed common system (→ Oil Refining, Chap. 4.2.1.1). For the storage of diesel fuel, *fixed roof tanks* are frequently used.

Small quantities of fuels can be stored in steel drums, steel cans or fuel-resistant plastic containers.

Transportation. Fuels can be transported *from* the refineries via pipelines, tank ships, rail tankers, or road tank trucks. In some countries mineral oil companies exchange base fuels from their refineries. The shortening of the transport routes allows cost saving and reduces safety risks.

In the refineries or depots, vapor recovery plants with a retention efficiency of ca. 99 % are sometimes employed for the filling of gasoline tankers [83]. When underground gasoline station tanks are being filled, displaced gasoline vapors are often returned to the tank trucks (vapor recovery stage 1). In Europe and the United States the emission of gasoline vapors is also controlled when car tanks are being filled by means of special dispensing nozzles (vapor recovery stage 2) [84].

Gasoline belongs to hazard class I, whereas diesel fuels are assigned to hazard class III because their flash point is > 55 °C. Hazard classifications for the transport of gasoline and diesel fuel are as follows:

Gasoline	
GGVS, ADR/RID	Class 3, number 3 b
IMDG Code	Class 3.1
UN no.	1203
ICAO/IATA-DGR	Class 3
Diesel fuel	
GGVS, ADR/RID	Class 3.3, number 31 c
IMDG Code	Class 3.3
UN no.	1202
ICAO/IATA-DGR	Class 3

8. Alternative Fuels

The search for alternative fuels is not new. During earlier efforts to introduce alternative fuels (e.g., during World War II or after the first oil crisis in 1973), concern about the extent of crude petroleum reserves or too great a dependence on oil-producing countries was predominant. Overcoming these problems was attempted by shifting fuel production from crude petroleum to other fossil energy sources. A true picture of the primary energy consumption can only be obtained by drawing up energy chains that take all conversion steps into account.

Liquefied Petroleum Gas (→ Liquefied Petroleum Gas). With liquefied petroleum gas (LPG) an additional fraction of crude petroleum (predominantly propane – butane) can be used as fuel for Otto engines. Because of the relatively expensive modification costs for vehicles and other disadvantages (higher volumetric consumption, lower engine power) use of LPG has become established in only a few places where taxation is favorable (e.g., the Netherlands, Italy, Japan, Australia).

Natural Gas (→ Natural Gas). Natural gas (predominantly methane) can also be used as an engine fuel either as compressed natural (CNG) or as liquefied natural gas (LNG). However storage in liquefied form requires considerable sophistication. Until now, natural gas is only used

as CNG on a broader scale in certain countries (Argentina, Italy, Russia). However, the relatively low carbon dioxide emission resulting from the high hydrogen content is favoring its use in the future. In Germany BMW has developed duel fuel vehicles for the use of CNG which are operated by fleet owners predominantly. Also a limited number of public service stations exist which offer CNG.

Fuels from Fischer – Tropsch Synthesis. *Synthetic gasoline* or *middle distillate* can be produced from coal or natural gas via synthesis gas from the Fischer – Tropsch synthesis [85]. This method, however, is often associated with a very poor overall energy efficiency and has been used in only a few special cases (Germany: World War II; South Africa: Sasol Process). However, new catalysts and different process conditions allow nowadays an improved energy efficiency, e.g., the Shell Middle Distillate synthesis process which produces a high cetane quality diesel fuel component from natural gas on small scale.

Methanol. Methanol is produced from synthesis gas [86], which can be obtained from crude oil, coal and even biomass. A number of experiments have been conducted on its use as a potential alternative fuel (Table 11). However, the use of almost pure methanol or of a 15 % mixture with gasoline has not yet found a practical application. On the technical side, problems in cold- and hotrunning performance and aldehyde emissions with cold engine require special attention whereas the specific power output and engine efficiency is advantageous in comparison to gasoline engines. From the economic point of view the high consumption and high engine adaption costs are a disadvantage [87 – 89].

Ethanol. The use of ethanol, which can be obtained form crude oil, coal and biomass, as an alternative fuel has been put into practice in Brazil. Both neat ethanol (hydrated at about 95 %) fuel and a 23 % blend in gasoline are marketed. Ethanol is produced mostly from biomass and could therefore potentially help reduce carbon dioxide emissions because of a closed carbon dioxide cycle. On the other hand catalytic exhaust gas treatment is also required even when ethanol is used because of other emissions (CO, HC, NO_x, and aldehydes).

Table 13. Properties of various vegetable oils in comparison with diesel fuel

Table 14. Energy storage in motor vehicles – energy equivalent to 50 L of gasoline

	Total tank volume, L	Tank mass, kg	Tank filling time, min
Gasoline	55	47	2
Diesel fuel	50	47	2
Methanol	103	88	2
Ethanol	84	72	2
Hydrogen (liquid)	330	94	7 – 80
Metal hydride (FeTi)	385	1175	20
Electricity, NaS battery	3565	3800	600

From the viewpoint of technical applications, the use of ethanol is somewhat less problematic than that of methanol [90, 91]; however, the high production costs and the huge cultivation area for biomass have kept its use as a fuel within narrow limits (see Table 12). Ethanol was used in Germany in former times ("*Reichskraftstoff*": 1/3 ethanol, 1/3 benzene, 1/3 gasoline).

Fatty acid methyl esters (FAME) are produced from vegetable oils by esterification. Especially rape seed oil methyl ester (RME) is used as a fuel for diesel engines on a small scale in some countries (mainly France, also Austria [92] and Germany). In principle vegetable oil fuels offer the advantages of greenhouse gas emissions benefits because of the closed carbon cycle, new outlets for agricultural products, the possibility of usage in standard diesel engine with minimum modification, and good biodegradability. On the other hand they offer little improvement over conventional diesel fuels in view of local air quality. Although exhaust smoke is somewhat lower, regulated and nonregulated emissions are scarcely different form those of diesel fuel. The global impact of the potential reduction in carbon dioxide emissions is limited by production capacity of RME which is predicted to rise but will still be less than 10 % of the diesel market [93, 94].

Vehicles fueled with RME show reduced power due to the lower calorific value and the higher viscosity as compared with diesel fuel. The volumetric fuel consumption is higher because of the oxygen content of RME. Technically, the use of rape seed oil fuel is also associated particularly with an increased engine wear under certain circumstances (caused by deposit formation) and poor cold flow performance (Table 13).

Hydrogen can be used either as an engine fuel or to feed fuel cells for on board generation of electricity. Neither of these concepts has gained a commercial status so far, partly because of the difficulties connected with the handling and storage of hydrogen (see Tables 14 and 15). For detailed information see → Hydrogen, Chap. 9.3.3.3.

Table 15. Environmental compatibility and availability of various fuels

Fuel	Environmentally sensitive substances	Availability
Gasoline (with catalyst)	CO_2, ozone among others	worldwide
Diesel fuel	CO_2, particle, NO_x, ozone	worldwide
LPG	CO_2, among others	some countries
Methanol		
fossil	CO_2, formaldehyde	locally possible in short time
biomass	formaldehyde	?
Ethanol (biomass)	acetaldehyde	Brazil
Vegetable oils	particles, among others	possible locally to some extent
H_2		
fossil	CO_2, NO_x, among others	?
nonfossil		?
Electricity		
fossil	CO_2, NO_x, among others	worldwide
nonfossil		possible to some extent

Electricity. For the use of electricity as an alternative fuel, global environmental compatibility is again determined by the production method. Electricity production based on fossil energy sources also leads to carbon dioxide emission as well as to the formation of regulated harmful substances. In addition, the total energy efficiency (based on the energy chain from production to utilization) of electrically driven vehicles is clearly lower than that of conventional fuels. However, the use of electric vehicles for areas of higher emission sensitivity (indoor areas, city centers) could become increasingly important. The *storage* of electricity in the vehicle represents a great problem because of the weight and the size of the batteries [95]. The development of efficient batteries such as the sodium – sulfur battery led to an increase in the energy density by a factor of ca. 4 in comparison with the lead – acid battery. However, compared to liquid fuels currently in use, there is still a considerable disadvantage in energy storage (and therefore in vehicle range). A solution to this problem is the onboard production of electricity by fuel cells which are currently under development (→ Fuel Cells, Chap. 4.1 Zero Emission Vehicle). Ultimately these can be fueled with

Table 16. Evaluation of alternative systems

hydrogen. Because of the handling and availability problems use of intermediate fuels such as hydrocarbons and methanol are currently discussed. The fuel cell technology has also the advantage of a noticeably improved efficiency compared to the combustion engine.

Hybrid Concepts. The introduction of alternative fuels is associated with considerable changes in the infrastructure that cannot be carried out in short term. For this reason, dualfuel hybrid concepts can greatly ease the introduction of new fuels. Up to now, prototypes for the alternative use of gasoline – methanol ("flexifuel" concept) [87], gasoline – hydrogen [96], and diesel – electricity [2, 97] have been developed. Gasoline – LPG and gasoline – CNG vehicles are commercially available in some areas, however, their market share is small mainly because of the additional initial costs and the reduced load capacity because of the second tank. At present, considerable discrepancy still exists between environmental compatibility and other important criteria such as suitability, availability, economic factors, and infrastructure (Table 16) [98].

6. Testing Strategies
7. Metabolic Activation
8. Types of Mutagenic Agents
9. Conclusions

[Top of Page]

1. Introduction

Mutations are changes in the composition of the genetic information that are passed on to the daughter cells. Mutagenic agents are, thus, chemical or physical agents that damage the genome and are also referred to as *genotoxic agents*.

However, changes in the genome are also the basis of evolution and may, in rare occasions, confer a selective advantage. Since evolution is a slow process, this may be observed in our time scale only in rapidly proliferating organisms, such as bacteria or viruses, which may acquire resistance towards antimicrobial or antiviral drugs by mutations. The overall majority of mutations are, however, either silent or detrimental.

There are a number of hereditary diseases that have been assigned to specific mutations in relevant genes (such as sickle cell anemia, hereditary breast cancer). Also, hereditary enzyme deficiencies have been associated with a mutated genetic code for the respective enzymes.

As an instrument in molecular biology site directed mutagenesis is a means to elucidate proteins by systematically introducing changes in the amino acid sequence.

Because mutagenicity is linked to carcinogenicity it is import to determine if a substance has a mutagenic potential. Genotoxic carcinogens are generally considered to have no safe dose, no threshold, and therefore stringent regulations are imposed on mutagenic agents minimizing human exposure to these agents to the lowest (reasonably) achievable level.

[Top of Page]

2. Mutagenesis

Mutations in a *germ line cell* result in changes in the genetic code, that are manifest in all cells of the off-spring and will be hereditary. However, these are very rare events. More common are mutations in *somatic cells* which may, in the worst case, lead to cancer or, if introduced in the developing embryo, to teratogenic effects.

Mutagenic agents may induce premutagenic lesions. These are transformed into mutations during DNA replication or by incorrect DNA repair processes (see below).

There are different types of mutations resulting from different types of damage in the DNA: gene mutations (point and frameshift mutations), chromosomal aberrations, and genome mutations.

2.1. Gene Mutations

Gene mutations are small changes in the DNA at the level of the bases. Upon replication a wrong nucleotide may be incorporated into the daughter strand and as a consequence the mutation is then passed on to the following generations of cells.

2.1.1. *Point Mutations*

By substitution of nucleotides the sequence of the bases is changed. This may be of no consequence when this mutation occurs in a nontranscribed region of the genome or when a silent mutation is introduced (because the genetic code is degenerate, different codons coding for the same amino acid). However, changing a codon may result in changes of the amino acid sequence of the resulting protein or the introduction of a stop codon.

Endogenous or exogenous agents may induce chemical changes in the bases, for example oxidative damage may result in deamination of adenine by nitrous acid. This deamination results in the incorporation of cytosine during replication and within two cell divisions a A–T base pair is converted into a G–C pair.

The most common damage induced by mutagenic agents is the covalent binding of a reactive, electrophilic metabolite to the nucleophilic DNA bases. Small *alkylating agents* bind to the O^6- or N7-position of guanine, the O^4-position of thymidine, or the N6, N3 or N7 of adenine. These small DNA adducts may lead to a mispairing upon replication and, thus, to the introduction of a point mutation (see Fig. 1.).

Figure 1. Normally guanine pairs with cytosine. Methylation at the O^6-position freezes the enolic form of guanine and may result in introduction of thymine in the opposing strand. Upon replication one of the daughter cells will, thus, contain a TA base pair instead of CG.

Polycyclic aromatic amines and nitroarenes are metabolically transformed and the ultimate electrophilic agents, the nitrenium ions bind to the C8-position of guanine and sometimes to the N^2- or N^6-exocyclic amino groups of the purine bases (Figure 2) (⟶ Carcinogenic Agents – Metabolic Activation).

Polycyclic aromatic hydrocarbons bind generally, upon metabolic activation, to the exocyclic amino groups of purine bases (Figure 2) but may also, after a one-electron oxidation, bind to the N7-position. Binding to the N7-position results in a weakening of the *N*-glycosidic bond and may lead to a loss of the base, resulting in an apurinic site.

Bivalent electrophilic agents, such as unsaturated carbonyl compounds, dicarbonyl compounds, or dihalogenated aliphatic agents may form cyclic adducts, binding to both exocyclic and endocyclic nitrogen atoms in the purine bases or cytidine.

2.1.2. *Frameshift Mutations*

Addition or elimination of bases to the sequence may result in a change of the reading frame. Generally, this leads to more serious changes in the resulting protein. A classical example is the congenital phenylketonuria, where the enzyme responsible for the conversion of phenylalanine to tyrosin is inactive due to a (hereditary) frameshift mutation.

Chemicals with a planar aromatic structure may intercalate into the DNA helix. This, but also covalent DNA adducts may result in a slip or an addition of one base during replication or DNA repair.

2.2. Chromosomal Aberrations

When parts of a chromosome end up in a different location in the same or a different chromosome, are lost or amplified, this is called chromosomal aberration. These types of damage are caused by breakages, deletions, or rearrangements during the cell cycle. The places where breaks or exchanges occur are usually not randomly distributed over the chromosome.

Chromatid-type aberrations include micronuclei, deletions, and interchromatid exchanges. *Chromosome-type aberrations* include bicentric chromosomes, terminal deletions, and acentric rings.

Microscopically, chromosomal aberrations may be observed after fixation and staining of the chromosomes during the metaphase stage of the cell cycle.

Agents inducing chromosomal aberrations are called *clastogens*, these include ionizing radiation and numerous chemical agents.

An example of a genetic disease resulting from structural chromosome aberrations is the Philadelphia chromosome. Here, a portion of the long arm of chromosome 22 is translocated to chromosome 9, an aberration, that is observed in the bone marrow cells of 90% of patients with chronic myeloid leukemia.

2.3. Genome Mutations

Genome mutations are also referred to as numerical chromosomal aberrations and involve a change in the number of chromosomes. *Euploidy* refers to a multiple of the complete set of chromosomes (haploid, diploid, triploid). *Aneuploidy* describes the situation when the number of some chromosomes is different from the normal diploid set or exact multiples of it. This may result from non-disjunction of chromosomes at anaphase or chromosome loss during cell division with an uneven distribution of chromosomes between daughter cells.

Aneuploidy may be induced by agents affecting the spindle apparatus, such as the drugs colchicine, taxol and vinca alkaloids. Also aneugenic environmental chemicals have been identified, for example high levels of the pesticide trichlorfon in the diet of mothers may be responsible for a cluster of congenital abnormalities including Down's syndrome, observed in a Hungarian village in 1990.

The frequency of aneuploidy in humans appears to be high: At conception a rate of about 16–50% is estimated. Most of the affected embryos are not viable and are spontaneously aborted. About one in 200 newborns displays aneuploidy, and a strong increase in this frequency is observed with the mother's age.

Trisomy of chromosome 21 results in Down's syndrome characterized by physical abnormalities, physical and mental growth retardation. This most common autosomal abnormality occurs with a frequency of about 1 in 600 children.

[Top of Page]

3. DNA Repair

A large variety of DNA repair enzymes continuously scan the DNA and replace damaged nucleotides. Therefore, despite the frequent occurrence of spontaneous or induced lesions (estimated to amount to several thousand in a typical mammalian cell each day) the number of mutations occurring is low and the genetic information is largely maintained intact.

DNA repair depends on the presence of a separate copy of the genetic information in each strand of the DNA double helix. A lesion on one strand can therefore be cut out by a repair enzyme and a good strand resynthesized using the undamaged strand as a template. There are a number of repair systems that identify and amend specific lesions in the DNA strand prior to the replication. For example, alkyl residues at the guanine O^6-position are being removed by a dedicated methyl transferase. In *base excision repair* an altered base is removed by a DNA glycosylase enzyme, followed by excision of the resulting sugar phosphate. In *nucleotide excision repair* a small region of the strand surrounding the damage is removed from the DNA helix as an oligonucleotide. In both cases the small gap left in the DNA helix is filled in by the sequential action of DNA polymerase and DNA ligase.

While some of these repair enzymes are constitutively expressed, others are inducible, in an adaptive response these enzymes are expressed when a DNA damage occurs.

DNA double strand breaks may be repaired by homologous recombination using the intact homologous chromosome as a template (this may lead to sister-chromatid exchanges) or by rejoining the ends of two DNA strands thereby losing several nucleotides at the joining point and introducing mutations.

In order to transform a DNA lesion into a mutation it is necessary that the DNA polymerase system is by-passing this lesion and is introducing a (wrong) base opposite the lesion in the daughter strain. The molecular mechanisms of these translesion DNA synthesis with a family of error-prone polymerases have been identified most recently.

[Top of Page]

4. Mutations and Cancer

Hereditary predispositions towards certain types of cancer have been linked to mutations in one of the two copies (alleles) of specific genes that humans carry in every cell. For example, a tumor suppressor gene may be damaged, such as BRCA1 in hereditary breast cancer. Induction of a mutation that damages the intact copy of this tumor suppressor will lead to the development of a tumor at a specific organ site.

Similarly, it is believed that mutations in oncogenes may lead to the development of malignant tumors. Generally, several genetic changes are necessary for a malignant tumor to develop. This high incidence of specific mutagenic events is possible only because in tumor cells the systems ensuring the integrity of the genome are also lost or damaged.

Also, chromosomal mutations (aneuploidy) play a major role in the induction and development of malignant neoplasms.

It has been proposed that the number and pattern of mutations, the so-called mutation spectrum, may be an indicator of the damaging agent. For example the fingerprint of mutations detected in several thousand of cancer cases in a specific gene (p53) is indicative of polycyclic aromatic hydrocarbons in cases of lung cancer, whereas in cases of skin cancer the majority of mutations resembled the damage induced by UV-irradiation.

[Top of Page]

5. Mutagenicity Tests

A large number of test systems can be employed to determine the mutagenic potential of an agent. Basically, these systems include in vitro tests in bacteria, yeast, or mammalian cells and in vivo short-term tests in experimental animals. The extent of testing required for new substances depend on the intended use (pesticide, drug, food additive, etc.) and the production volume.

Several tests have been standardized and the testing procedures are laid down in OECD Guidelines, EU test guidelines, or by the Environmental Protection Agency of the USA.

The principles of these tests are described in detail in ⟶ Toxicology – *In Vitro* and *In Vivo* Short-term Tests for Genotoxicity.

5.1. Microbial Tests

Most commonly the so-called *Ames test* is performed. Here gene mutations (point mutations or frameshift mutations) are recorded in a battery of mutated *Salmonella typhimurium* strains that require histidine. With or without addition of external metabolic activation (added homogenate of rat liver) reverse mutations are detected by regaining histidine-prototrophy (OECD Guideline 471, EU test guideline B.13/14, ⟶ Toxicology – Microbial Tests for Mutagenicity).

5.2. Eukaryotic In Vitro Tests

Whereas microbial tests are easier to conduct, assays involving mammalian cells are generally considered more relevant for the prediction of animal or human in vivo effects and also allow detection of clastogenic or aneugenic potency.

5.2.1. *Mammalian Gene Mutagenicity Tests*

Most commonly the V79 cell line (Chinese Hamster) or the mouse lymphoma cell line L5178Y $TK^{+}/^{-}$ are employed. These tests may be conducted with or without external metabolic activation. In principle, mutations in the hypoxanthine-guanine phosphoribosyl transferase gene (HPRT) are detected in V79 cells. This gene, which is a available only in one copy because it is located on the X chromosome, confers susceptibility towards purine derivatives such as 6-thioguanine. Similarly, the mouse lymphoma cell line L5178Y $TK^{+}/^{-}$ possesses only one copy of the gene coding for thymidine kinase, an enzyme involved in nucleotide metabolism and leading to susceptibility towards the pyrimidine derivative trifluorothymidine. Inactivation of these enzymes (by mutation) leads to insensitivity towards these agents. Cells with a mutation survive and may be scored as growing clones.

In the mouse lymphoma test small mutant colonies are considered the result of chromosome damage while large mutant colonies are considered the result of gene mutations (OECD Guideline 476, EU test guideline B.17, ⟶ Toxicology – Eukaryotic Tests for Mutagenicity).

5.2.2. *In Vitro Cytogenetic Assays*

Chromosomal aberrations are analyzed microscopically in cell populations in metaphase. Mostly cells of the Chinese hamster such as V79 and CHO are utilized but also human lymphocytes and mouse lymphoma cells. Metaphase chromosomes are stained and inspected for rearrangements. In the *sister-chromatid exchange assay*, chromosomes are differentially stained and inspected for the presence of exchanges between sister chromatids.

In recent years the *micronucleus assay* has become more popular: Micronuclei (MN) may be formed during the cell division and may arise from a whole lagging chromosome (aneugenic event leading to chromosome loss) or an acentric chromosome fragment detaching from a chromosome after breakage (clastogenic event). The MN test may be performed with different cultured mammalian cells and involves the treatment of cells with the actin polymerization inhibitor cytochalasin B to identify cells that divide as binucleate cells. Micronuclei are detected microscopically. By means of kinetochore-antibody staining or fluorescence in situ hybridization they may be differentiated into micronuclei containing a whole chromosome or an acentric chromosome fragment, indicating aneugenic or clastogenic activity, respectively, of the test compound (OECD Guideline 473, EU test guideline B.10, ⟶ Toxicology – Tests for Chromosome Aberrations (Cytogenetic Assays)).

5.3. In-Vivo Tests

5.3.1. *Micronucleus Assay*

As the in vitro micronucleus test, this assay tests mutagenic effects on the chromosome and genome level, detecting clastogenic and aneugenic agents. The in vivo micronucleus test is generally performed in mice, and the tissues most often assessed for frequency of micronuclei are bone marrow and peripheral blood. Erythrocytes are the cells that are scored in the bone marrow or the blood for presence of micronuclei. Because they are constantly produced from precursor cells and the nucleus is expulsed from the cell immediately after full differentiation is accomplished, erythrocytes are an ideal cell type for a micronucleus test. If a stem cell is damaged by a chemical and a micronucleus is formed as a consequence of this damage, the micronucleus remains in the cell after the main nucleus has been expulsed and can be observed microscopically.

Mouse bone-marrow micronucleus tests typically employ one to three treatments with the chemical under study; with doses extending up to the maximum tolerated dose. The route of administration in these short-term tests is usually either intraperitoneal injection or oral gavage. Based on the cell cycle and maturation times of the erythrocytes, harvesting of the

bone marrow usually occurs 24 h after the final dosing. At that time, about 50% of the erythrocytes in the bone marrow are immature, newly formed erythrocytes, and these are the cell types that are checked for presence of micronuclei. The bone marrow is flushed from the femurs and spread onto slides. The slides are dried, fixed, and stained with a fluorescent DNA-specific stain that easily illuminates any micronuclei that may be present. 2000 polychromatic erythrocytes (PCEs, or immature erythrocytes) are scored per animal for frequency of micronucleated cells. In addition, the percentage of PCEs among the total erythrocyte population in the bone marrow is scored for each dose group as a measure of toxicity. Short-term studies that give positive results are repeated to confirm the response.

Critical parameters in analyzing micronucleus test data are the number of animals per dose group (a minimum of three is required); dose levels and number of doses administered; route of administration; tissue and cell type analyzed; sample time (interval between last dosing and harvesting of cells for analysis);, frequencies of micronucleated cells in the negative and positive controls; and the results of the statistical analyses. In the case of a negative result it is important to establish that the test chemical reached the target organ (bone marrow), which may be verified by signs of bone-marrow toxicity.

5.3.2. *Indicator Tests*

Assays that measure damage to DNA may be performed either in vitro or in experimental animals. These tests include detection of *unscheduled DNA synthesis* (UDS), indicating the repair of damaged DNA. The test is most commonly performed in primary hepatocytes in vitro or in hepatocytes following in vivo treatment (OECD test guideline 486, EU test guideline B39).

The formation of DNA adducts may be analyzed by ^{32}P-postlabeling analysis. Here covalent modifications are analyzed chemically with a sophisticated procedure involving enzymatic DNA hydrolysis, enzymatic labeling with ^{32}P-phosphate and chromatographic separation of labeled modified nucleotides (⟶ Toxicology – Test Systems Providing Indirect Evidence for DNA Damage.)

The analysis of DNA strand breaks may be accomplished by single cell electrophoresis (comet assay). Here nuclei are exposed to an electric field under DNA denaturing conditions in an agarose gel. Damage to DNA results in DNA fragments that move faster in the gel. This can be visualized upon fluorescence staining and microscopically scored.

The advantage of short-term in vivo assays such as ^{32}P-postlabeling analysis and comet assay is that a number of organs may be assayed in parallel and genotoxic activity testing is not confined to one organ such as the liver in UDS tests or bone marrow in the case of the micronucleus assay.

The more common application of these, liver and bone marrow specific, tests is based on the assumption that mutagens exhibit a general genotoxicity which would be detectable in all organs. However, this is contradicted by the organ specificity observed by some chemical carcinogens.

5.3.3. *Transgenic Animals*

Assays based on transgenic animals such as Muta Mouse or Big Blue Mouse (and rats) allow determination of genotoxic potency in any organ. These commercially available animals have been genetically modified so that each cell contains a shuttle vector containing several copies of the lactose operon of *E. coli*, lacZ or lacI, respectively. These serve as indicators of gene mutations. Briefly, these animals are treated with a test compound, animals are sacrificed, DNA is isolated after a certain delay period, and the shuttle vector is transferred to *E. coli*. Detection of mutations in the shuttle vector sequences is accomplished by white/blue selection of growing bacteria in plates containing appropriate indicators.

These assays show a high degree of correlation with conventional in vitro gene mutation assays and also mutagenic activity was detected in target organs of numerous carcinogens. While these assays are detecting mutations in nongenomic DNA and may not detect chromosomal or genome mutations, there are new developments under way such as the gpt delta mouse, for example, that may be capable of detecting large deletions induced by clastogens.

[Top of Page]

6. Testing Strategies

Depending on the type of substance there are guidelines and legislation, for example in the European Union, that regulate the requirements for genotoxicity testing.

Basic testing for genotoxicity includes one gene mutation assay (mostly a bacterial assay) and one in vitro mammalian assay (most commonly the in vitro chromosomal aberration test). If these tests are negative, there is no further testing required for existing chemicals and cosmetic ingredients.

A third in vitro test (mammalian cell gene mutation test) is required for plant protection products, biocides, food additives, food contact materials, and human pharmaceuticals.

For human pharmaceuticals and veterinary drugs for food producing animals, basic testing includes a bacterial gene mutation assay, mammalian cell assay (mouse lymphoma assay or in vitro chromosome aberration), and an in vivo assay (testing chromosomal aberration or micronucleus formation).

New chemical substances require testing depending on tonnage of production.

If these basic tests are consistently negative the test substance is considered nonmutagenic. However, further testing is required in the case of positive findings in one or all basic assays conducted.

Generally, in vitro tests are preferred to tests in animals in line with animal welfare considerations. However, in vivo test are more important in the final assessment of a test substance, for examples a positive result in a microbial assay is generally overruled by negative outcome of one or more in vivo assays.

In order to assess a test substance the judgement of an experienced toxicologist is required.

[Top of Page]

7. Metabolic Activation

Strictly speaking most so-called mutagenic chemicals are not mutagenic themselves but, in order to exhibit their genotoxic activity require metabolic activation. By enzymatic transformation reactive metabolites are formed, such as α-hydroxy derivatives of *N*-nitrosamines, hydroxylamines from aromatic amines and nitroarenes, epoxides from hydrocarbons, or radicals that are capable of binding to the DNA. Covalent binding to DNA results in DNA adduct formation (Fig. 2.). These adducts are mostly removed by repair mechanisms but may result in the introduction of mutations (⟶ Carcinogenic Agents)

Figure 2. Prototypes of DNA adducts: Major deoxyguanosine-adducts formed by benzo[a]pyrene (via its diol-epoxide, BPDE-dG), 4-aminobiphenyl (C8-ABP-dG), hydroxyl radicals (8-OH-dG) and *N*,*N*-dimethylnitrosamine (N7-Me-dG). Alkylating agents may also modify thymidine such as O^4-Me-dT. The thymidine dimer formed is the major lesion formed by UV-light and the N^2-deoxyadenosine adduct is induced by the herbal carcinogen aristolochic acid I (AAI-dA).

UV- or visible light may also serve as an activating agent. In assays investigating photomutagenicity treated cells are exposed in vitro to a source of UV(and/or visible) light. A number of examples of agents inducing gene mutations upon photoactivation have been reported. These agents include polycyclic aromatic hydrocarbons, and fluoroquinolones. Also clastogenic activity may be induced by photoactivation for example in the cases of 8-methoxypsoralen or chlorpromazine. These effects are especially relevant for ingredients of cosmetic products.

[Top of Page]

8. Types of Mutagenic Agents

The most prominent mutagenic agents are also carcinogenic and are described in Carcinogenic Agents. Computer programs are available that, based on biological data, assess chemical structures for functional elements (“alerting structures”), which may act as mutagens. (⟶ Carcinogenic Agents – Modeling). These programs are useful to scan large libraries of chemicals being tested early in high throughput drug development, but even highly sophisticated calculation methods are presently not able to replace biological testing.

Members of the following classes of chemical compounds have been identified as mutagenic:

- *N*-Nitroso compounds
- Benzene
- Polycyclic aromatic hydrocarbons
- Nitroaromatic compounds
- Aromatic amines
- Halogenalkyls
- Aldehydes
- Alkylating agents
- Metals

In addition, a number of natural compounds and mixtures show mutagenic potential. Mutations can also be induced by oxygen damage. *Physical mutagenic agents* include nonionizing and ionizing radiation.

Aneugenic agents with no direct genotoxic activity are listed below. These may act by inhibition of repair enzymes, cell cycle control or apoptosis related proteins, tubulins of the mitotic or meiotic spindle or interference with detoxification or activating enzymes:

- Benomyl
- Cadmium chloride
- Carbendazim
- Chloralhydrate
- Colchicine
- Diethylstilbestrol
- Griseofulvin
- Hydroquinone
- Vinblastine

[Top of Page]

9. Conclusions

In addition to the application as short-term test to detect the mutagenic potency of test chemicals, assays such the micronucleus test, comet assay or ^{32}P-postlabeling are applied as biomarkers in molecular epidemiological studies. Increased levels of DNA adducts have been observed in cohorts occupationally exposed, e.g., to polycyclic aromatic hydrocarbons or styrene, to aflatoxins in the diet, to tobacco smoke, or to genotoxic drugs (including chemotherapeutic agents or herbal drugs).

In vivo animal experiments reflect the human situation only to a certain extent but generally the predictive value of animal assays is believed to be quite high. In contrast, in vitro assays are highly artificial and several aspects such as metabolic activation and toxicokinetics are not included. Therefore, data from in vivo assays are considered more relevant for the evaluation of a test chemical. In vitro assays are, however, indicative of the mechanism of action of a mutagen.

Antimutagenic agents inhibit or reduce the activity of mutagens. These may act by inducing detoxifying mechanisms, by antioxidative or receptor antagonism.

Co-mutagens are not mutagenic but may in combination with other agents increase mutagenic activity. Here, induction of activating enzymes, inhibition of detoxifying mechanisms, or formation of mutagenic metabolites is involved.

There are also compounds that are positive in several short-term tests for mutagenicity but failed to induce tumors in animal carcinogenicity studies. Examples are flavonoids such as quercetine or *p*-phenylendiamine. This may relate to high doses, that have been tested in vitro but are too toxic to be administered in vivo. However, these cases are highly disputed in the scientific community.

On the other hand there are carcinogenic agents that act via a nongenotoxic mechanism of action, such as mitogenic agents, tumor promoters, or hormones (⟶ Carcinogenic Agents).

Most genotoxic agents inducing gene mutations are also clastogenic. There are aneugenic agents that act solely by inhibiting the synthesis and assembly of the mitotic spindle, with no direct activity on the DNA, such as the methyl benzimidazole carbamate pesticides benomyl and carbendazim. Other indirect mechanism may involve inhibition of DNA repair (e.g., action of cadmium).

Based on theoretical considerations, *indirect genotoxins* are believed to be thresholded, i.e., there exists a safe exposure level. DNA damaging agents (*direct genotoxins*) are considered to act without a threshold, i.e., already a single molecule could induce mutation and cancer albeit with a exceedingly small but finite probability. Therefore, it is important to identify the mechanism by which a mutagenic agent is exerting its activity.

Molecular modeling is used to understand the characteristics of molecules and to design new molecules in industry and elsewhere. The computer-based techniques of molecular modeling include molecular mechanics, molecular graphics, and many other methodologies of computational chemistry. Most large research-based companies involved in molecular science, particularly pharmaceutical companies, use molecular modeling daily.

1. Definitions

In the narrowest sense used by some chemists, molecular modeling refers to conformational energy calculations and interactive manipulation of three-dimensional (3D) molecular structures on a computer screen. For instance, an early definition of molecular modeling was offered by TROST: "Molecular mechanics, [which is] the empirical computation of conformational energy, combined with computer graphics" [2]. This definition reflects the perspective of many organic chemists who want the computer to help them better understand the 3D shapes of molecules. HOPFINGER, a computational chemist, suggested a somewhat broader definition: "The generation, manipulation, and/or representation of molecular structures and associated physicochemical properties" [3]. From the perspective of a chemist in industry (DuPont), an even broader definition was set forth: "Virtually anything which is done to depict, describe, or evaluate any aspect of the properties or structure of a molecule that requires the use of a computer" [4].

The terms computational chemistry and molecular modeling are intertwined and are often used interchangeably in industry. Computational chemistry has been broadly defined as "those aspects of molecular research that are expedited or rendered practical by computers" [5]. Definitions for molecular modeling and computational chemistry have been discussed on the Internet (see, e.g., [6]). Deliberations of an IUPAC working party [7] resulted in a recommendation to define computational chemistry loosely as "a discipline using mathematical methods for the calculation of molecular properties or for the simulation of molecular behavior. It also includes, e.g., synthesis planning, database searching, and combinatorial library manipulation". The IUPAC group defined molecular modeling as "the investigation of molecular structures and properties using computational chemistry and graphical visualization techniques in order to provide a plausible three-dimensional representation under a given set of circumstances".

2. Purpose of Modeling

Modeling involves working with what is usually a simplified description of a system. Despite the simplifications, the model should capture the essence of a particular object, property, or process of interest. The models help scientists sort out complex relationships between variables. Being able to devise and use good

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

models can help rationalize experimental data. Modeling can be used to estimate values of molecular properties in cases where experiment is difficult or impossible [8].

It is important to keep in mind that because of the mathematics involved, modeling requires attention to quantitation and detail. When molecules are being generated, manipulated, represented, depicted, etc., it is important to strive for realistic molecular structures and associated physicochemical properties. Although it is fairly easy to display a molecular structure on a computer screen, the model should closely represent an experimentally determined structure, so that any conclusions that are derived from the model are useful. State-of-the-art hardware and software make it easy for even the novice to create a structure on a computer screen, but does it mean anything? It may not be immediately apparent from just looking at a structural depiction that some bond lengths are too short or too long, for instance. A bench chemist may be used to writing chemical structures without the hydrogen atoms, but to minimize the quantum mechanical energy of a molecular structure leaving off hydrogen atoms will lead to useless results. Proper use of the models requires an appreciation of quantitative details and the underlying theory.

3. Brief History

Models of molecules have been around for a long time. Chemists have used hand-held molecular models to help them visualize conformation and understand stereochemistry. These models were built of cork, wood, metal, or plastic. Well-respected types, such as Dreiding or CPK, were once familiar in most chemistry laboratories. Because of the prevalence of computers today, some young students may not have ever heard of these models unless they happen to look in some old books and journals. Today computers perform many of the functions of the hand-held models and can do much more.

Theoretical chemistry had its origins in the quantum mechanics developed in the 1920s. However, it was not till the late 1950s that the early slow computers became available to research chemists. Two camps of quantum chemists developed [9]. One camp was interested in rigorous applications of the theory, which of necessity were confined to small molecules of only a few atoms, too small to be of interest to most industrial chemists. This ab initio (from first principles) research was mainly of interest to theorists, spectroscopists, and physicists. The other camp was willing to forego theoretical purity to render the methods applicable to molecules large enough to be of interest to a wide body of chemists. The latter, so-called semiempirical approach began to be applied to molecules of biological and commercial interest.

Simultaneously, organic chemists, starting with WESTHEIMER, ALLINGER [10], and others, recognized the importance of understanding the conformations of organic molecules and developed empirical methods for computing the relative energies of molecular structures. Likewise, protein chemists, such as SCHERAGA [11], became interested in empirical modeling because it allowed study of the conformations of polypeptides and proteins. The empirical or molecular mechanics methods were faster than either ab initio or semiempirical quantum mechanical methods and opened the door to computer simulations of large biomolecules, including enzymes, nucleic acids, and materials. The use of molecular mechanics spread in the 1970s and continues to grow [12, 13].

Other physical organic chemists were interested in the lipophilicity of molecules because of the relevance of this property to drug action. Starting in the 1960s, computational methods were developed for estimating the partitioning of solutes between aqueous and nonpolar solvents [14]. These methods have been used frequently to quantitate the relationship of biological activity and chemical structure.

Visionary scientists in the pharmaceutical industry recognized in the 1960s that theoretical modeling could add value to their company's research programmes and convinced their managers to hire one or two computational chemists in the 1960s and 1970s. However, it was not until the 1980s that industry broadly recognized the need to hire scientists to do molecular modeling. The field blossomed because of four factors:

1) Mini- and supermini-computers, particularly the VAX series from Digital Equipment Corporation.

2) High-resolution computer graphics terminals and workstations, such as the Evans and Sutherland Picture System.
3) User-friendly, multifunctional computational chemistry software packages.
4) The promising results of the initial modeling efforts.

Today the use of molecular modeling continues to grow due to:

1) Ever more powerful workstations (running UNIX) and personal computers (running Windows or Linux) at low relative cost.
2) Modern computational chemistry software with graphical user interfaces (GUI).

All major research-based pharmaceutical companies and many biotechnology companies employ computational chemists for molecular modeling. Large companies may have hundreds of scientists using molecular modeling. For a more detailed history of the use of computers and software in the pharmaceutical industry, see [15]. In addition, molecular modeling groups can be found in the agrochemical, chemical, and other industries.

Figure 1. A search of the Chemical Abstract Service CAPLUS database indicates that as of late 2005 more than 3100 original research papers and nearly 400 book chapters and review articles are indexed as relevant to the two terms molecular modeling and computer. The number published annually is plotted.

Thousands of papers have been written about the methods and uses of molecular modeling. The growth in the annual number of publications can be seen in Figure 1. Use of the term molecular modeling with respect to computers increased in the 1980s, accelerated in the 1990s, and continues to grow. The most popular venues for these publications have been the Journal of Medicinal Chemistry, the Journal of Molecular Graphics and Modelling, and the Journal of Computer-Aided Molecular Design. Many books and reviews of molecular modeling continue to appear, see, e.g., [16 – 28].

4. Methodologies of Molecular Modeling

Molecular modeling entails a wide variety of complex, computer-based methods. These methods include ones for determining properties, accessing prior knowledge about them (databases), and analyzing data. Brief qualitative descriptions of some of these methods are presented.

Standard molecular modeling programs [29] are in use at many companies and universities, whereas other software packages, especially those specialized for molecular structure database management and drug design, are found mainly in the pharmaceutical industry because of their expense. Compilations [30, 31] have presented brief descriptions of programs, information about developers and vendors, and resources on the World Wide Web (WWW). More recent information about software can be found with the Google search engine on the WWW. A number of databases (e.g., PubChem) and software tools are in the public domain. Again, a search of the WWW will reveal both free and commercial resources.

4.1. Computer Graphics

The most important component of molecular modeling is computer graphics because this is the interface between the user and the computer. Molecular structure being the universal language of chemists, a user sitting at a computer can draw a molecule to be modeled on the screen using a “point and click” paradigm. Program options can be set up through a graphical user interface (GUI). After a calculation (such as described in the sections below) is complete, the results may be examined visually on the computer screen.

The complexity of molecular models makes high resolution, color, and stereo graphics highly

desirable, if not essential [32]. The simplest graphical depiction of molecules has lines representing bonds connecting points representing atoms. More complex graphics representing molecules as solid objects with colored or translucent surfaces help to convey molecular properties that pertain to each region of the molecule. Examples of computer graphics are shown in Figures 2 [33] and 3 [34 – 37].

Figure 2. Molecular graphics of raloxifene (Evista), a drug for preventing osteoporosis and other health problems in women. Atoms are color-coded by element: carbons in black, oxygens in red, hydrogens in light blue, etc. The upper image is a stick figure; the lower image shows the electrostatic potential color-coded on an outer contour of the electron density distribution. Red denotes regions with high concentration of negative charge that would strongly attract a positive probe point charge; regions with a slight excess of electron density are in yellow; regions with a slight deficiency of electron density are in green; regions that would strongly repel a positive probe point charge are in blue.

Computer graphics is also used to visualize the results of statistical analyses. Complex response surfaces can be color-coded to show how several variables relate to each other [38]. The quantum chemical and molecular simulations methods (see below) are computationally intense and generate large quantities of data; computer visualization turns the data into something meaningful to chemists.

4.2. Databases

Almost all pharmaceutical and chemical companies have their own proprietary databases of compounds that have been synthesized or purchased for testing in various biological assays. In addition, there are commercial databases of compounds, such as the Chemical Abstracts Service's Registry database, and MDL Information Systems' Available Chemicals Directory (ACD). Industrial chemists use these databases to answer questions such as where can a compound be purchased, or has a chemical structure already been synthesized, or what compounds exist that are similar to a structure of interest?

Figure 3. Stereo image of a possible superposition of four nonpeptide angiotensin II receptor antagonists.
a) losartan (green); b) eprosartan (light blue); c) Lilly's LY301875 (red); d) 3-*n*-butyl-5-[(2-carboxybenzyl)thio]-4-[[2′(1*H*-tetrazol-5-yl)biphenyl-4-yl]methyl]-4*H*-1,2,4-triazole (yellow). This overlay is based on alignments of the alkyl chains (right), aromatic rings (bottom), acidic groups (tetrazole or sulfonic acid) (bottom), and hydrogen bonding groups (top).

Database management tools specifically designed to handle chemical skeletons are used for rapid storage and retrieval. There are two types of molecular structure database: two-dimensional and three-dimensional. The 2D type stores atoms (chemical elements) and connectivity information (which atoms are bonded in a molecule). The 3D type stores, in addition, the x, y, z Cartesian coordinates of each atom in a molecule.

Structures determined by X-ray crystallography [39] or NMR spectroscopy [40] are stored in 3D databases. International repositories of the atomic coordinate data are available [41], such as the Cambridge Structural Database (CSD) for small organic and organometallic compounds, and the Protein Data Bank (PDB) and the Nucleic Acid Database for biomacromolecules. The structures can be used as starting points for molecular modeling experiments.

4.3. Conformational Modeling

Shape and energy are two molecular properties by which chemists understand how compounds interact and react. The properties are thus important in the pharmaceutical and agrochemical industries, where compounds must be found that will bind specifically to a receptor mediating a biological effect. To bind to a receptor, a molecule must have the shape — or the ability to adopt the shape — required for fitting into the receptor site. Most molecules are flexible, and at room temperature they are constantly undergoing conformational changes. The lowest energy structure is the global minimum one, but it may have no relevance to the conformation adopted upon receptor binding. As more ligand – receptor structures become solved by X-ray crystallography, it has become clear that is it not uncommon for the bioactive conformation of a ligand to be several kJ/mol higher in energy than the global minimum conformation. This situation arises because, when a ligand interacts with a receptor site, additional interatomic forces, not present in aqueous solution, occur that can induce the ligand to adapt its shape for better fit. The other forces arise from electrostatics, hydrogen bonding, van der Waals interactions, and hydrophobic effects. However, if too much energy is required to force a molecule to adopt a conformation required for receptor recognition, it is unlikely that the molecule will bind well.

The process of exploring all the conformations a molecule can adopt is conformational searching [42]. This involves molecular modeling techniques to map out the potential energy surface of a molecule, which describes the energy of the molecule as a function of the spatial location of its atoms. One type of conformational searching is systematic searching, where, as the name implies, the torsional angles at the rotatable bonds are varied systematically in increments. Another type is the Monte Carlo method, in which the geometrical variables are varied randomly, and the energy of each random conformation is calculated [43]. These and other methods for conformational searching tend to be computationally intensive and become prohibitively lengthy for molecules with more than about ten rotatable bonds. Energy evaluation during a search can be done with a force field or quantum chemical method (see below), although the force field methods are preferred because of their much greater speed and comparable accuracy.

Once the conformations have been determined, then molecular shape comparisons are possible. Molecular modeling offers several ways to compare and superpose molecular structures: alignments can be made by least-squares fitting of atoms or of projections to hypothetical hydrogen bonding points. Molecules can also be aligned based on their "surfaces" (e.g., the van der Waals surface) [44] or a computed field (measuring, e.g., steric, electrostatic, or lipophilic effects). Overlaying molecules is easy with computer models and is one of the most common applications of modeling.

4.4. Quantum Mechanical Modeling

Quantum mechanics (QM) is embodied in the Schrödinger equation, $H\Psi = E\Psi$, where H is a mathematical operator of kinetic and potential energy terms, Ψ is the wavefunction describing the positions of particles (electrons and nuclei) in a system, and E is the energy of the system [45, 46]. In molecular orbital (MO) theory, which has been the most common implementation of quantum mechanics used by chemists, electrons are distributed around the atomic nuclei until they reach a so-called self-consistent field (SCF), that is, until the attractive and repulsive forces between all the particles (electrons and nuclei) are in a steady state, and the energy is at a minimum. By computing the energy of different nuclear configurations, the lowest energy structure can be found. Such geometry optimization is useful because the bond lengths and bond angles that give the lowest energy are usually closest to what is observed experimentally. It has been pointed out that reliable reproductions of potential energy surfaces of flexible molecules sometimes need more stringent SCF and optimization convergence criteria during the calculations [47].

In ab initio MO calculations, very few approximations are made [48], and in principle they have the best ability to give agreement with experimental molecular properties. The electron density is represented by distributing it among certain standard sets of mathematical functions, called basis sets [49]. The different levels of ab

initio theory are referred to as "theoretical models" [50]. Unless the basis set is adequate, there is no great advantage of doing a calculation ab initio. Sometimes electron correlation (the phenomenon of electrons avoiding each other) and relativistic effects must be included in a calculation to get good results. Of the various quantum methods available, ab initio calculations are preferred, but unfortunately these calculations are sometimes too slow for molecular modeling applications of interest to industrial chemists. In certain situations, however, a molecule with several hundred atoms can be treated by an ab initio method [51, 52]. Large molecular systems are best left to one of the force field approaches (see Section 4.5).

In semiempirical MO calculations, additional approximations are made, such as treating only the outermost (i.e., valence) electrons while assuming the core (inner) electrons neutralize part of the nuclear charge [53 – 55]. Parameters in semiempirical theories are set to reproduce as closely as possible selected experimental molecular properties of well-studied compounds. However, parameters that work well at reproducing a small set of data are usually not robust enough to reproduce a broad range of properties and compounds. Semiempirical methods are sometimes used for "intermediate-sized" molecules (20 - 200 atoms). Semiempirical methods can sometimes predict molecular properties adequately, at least for similar molecules in which the effects of systematic errors are minimized.

A third implementation of QM is density functional theory (DFT) [56 – 59]. It is particularly useful in materials applications and is increasingly used for determining molecular properties. DFT is popular because it offers a compromise: it is faster than ab initio methods and more accurate than semiempirical methods. In DFT, the energy of a molecule is determined from the electron density, not from an MO wavefunction. Whereas ab initio theory includes the kinetic energy of the electrons and the potential energies of electron-electron repulsion and electron-nuclear attraction, DFT also includes an energy term called exchange-correlation that improves the result.

Electronic structure calculations are suited for predicting a variety of molecular systems (ground states, excited states, and transition states) and properties (optimum bond lengths and bond angles, conformational preferences, ionization potentials, electron affinities, charge distributions, hydrogen bonding, etc. [60, 61]). Molecular similarity can be calculated based on electronic structure [62]. Many types of reactions have been modeled (see, e.g., [63]). For modeling an enzymatic reaction, a chemically reasonable subset of atoms in the active site can be treated quantum mechanically and the rest of the system can be treated empirically [64]. This is the so-called quantum mechanics/molecular mechanics (QM/MM) approach.

Although the charge on an atom is not an experimental observable, charge distributions are of great interest to chemists [65, 66]. From a wavefunction, one can calculate the molecular electrostatic potential (MEP), which is an energy of attraction or repulsion experienced by a hypothetical unit charge as it moves in the vicinity of a molecule [67]. The MEP provides a model of how one molecule looks to another as they approach, such as when a ligand is approaching a receptor.

4.5. Force Field Modeling

In molecular mechanics (MM), as well as in molecular dynamics (MD) and Monte Carlo (MC) simulations, an empirical force field (FF) describes how the energy of a molecule changes as a function of bond lengths l, bond angles θ, and torsional angles ϕ. Atoms are treated as points in space except for the van der Waals term, which represents the atoms as spheres with soft surfaces. A set of energy terms and associated parameters is called a force field (FF) [68]. Simpler FFs assume harmonic force constants. The energy is a combination of bond stretching/compression, bond angle bending, torsional, van der Waals, and electrostatic forces that tend to hold the atoms at their equilibrium positions [69 – 73].

$$E_{\text{total}}=E_b+E_\theta+E_\phi+E_\tau+E_{el}+E_{vdw}$$

$$E_b=\sum\nolimits_{\text{bonds}} k_b(l-l_0)^2$$

$$E_\theta=\sum\nolimits_{\text{bond angles}} k_\theta(\theta-\theta_0)^2$$

$$E_\phi=\sum\nolimits_{\text{dihedral angles}} k_\phi[1+\cos(n\phi-\delta)]$$

$$E_r = \sum_{\text{improper angles}} k_\tau (\tau - \tau_0)^2$$

$$E_{el} = \sum_{i,j>i} \frac{q_i q_j}{\varepsilon r_{ij}}$$

$$E_{vdw} = \sum_{i,j>i} \frac{A_{ij}}{r_{ij}^{12}} - \frac{B_{ij}}{r_{ij}^{6}}$$

Here the force constants are the various parameters k, the "natural" bond lengths and angles are indicated by the subscript zero, ε is the dielectric constant, r_{ij} is the interatomic distance between atoms i and j, and "improper" angles τ refer to a mathematical trick to keep sp^2 atoms from deviating too far from planarity. Partial charges are denoted by q. n is 1, 2, or 3 depending on the periodicity of bond rotation, and δ determines where the minima occur. A_{ij} and B_{ij} are parameters determining the depth and distance of the energy minimum in a van der Waals interaction, which is attractive at long range and repulsive at short distances. The van der Waals and Coulombic interactions are summed between nonbonded atoms, whereas the other FF terms involve atoms bonded to each other. In better force fields, additional terms take into account anharmonicity and special electronic effects. The FF parameters are calibrated to reproduce experimental geometries and relative energies.

In molecular mechanics, the objective is to compute the energy of a molecular structure and/or to minimize the energy as a function of geometrical degrees of freedom, i.e., the potential energy surface. The computed energy reflects how far a geometrical arrangement around each atom deviates from an idealized bonding situation. A "better" geometry has a lower energy. Optimization methods [74] are used for energy minimization.

The MM model is conceptually simple, gives quite accurate molecular structures, and provides its information at least an order of magnitude faster than do QM methods. These strengths make MM well suited for treating both small and large molecules. Limitations of MM are that it requires empirical parameters to describe each "spring", and predictions depend on the care with which parameterization has been done, just as in quantum calculations where the results depend on the adequacy of the basis set and theoretical model.

Molecular dynamics (MD) simulations give information about the variation in structure and energy of a molecule over an interval of time [75, 76]. In MD, atoms move according to Newton's equations of motion (force = mass × acceleration, and force = negative gradient of potential energy). Thus, atoms under the most strain move fastest and farthest. To satisfactorily solve Newton's equations requires extremely short time steps, typically only 1 fs (10^{-15} s). If the time increment is too long, atoms can come too close in each step, and the energy of interaction from the FF become so high that the system becomes erratic in subsequent steps [77].

MD simulations are useful in computing accurate relative free energies. Free energy perturbation (FEP) or thermodynamic cycle calculations simulate the mathematical conversion of one molecule to another [78 – 80]. By changing the FF parameters in tiny increments from those of one chemical structure to those for another similar structure, the change in free energy can be accurately simulated. Assuming the incremental changes are small enough that the molecular system stays in equilibrium, FEP calculations can predict relative binding energies of two similar ligands associating with a receptor. Although in principle FEP calculations should be useful for testing molecular design ideas, in practice the calculations may be too slow for many industrial applications [81, 82].

Monte Carlo (MC) simulations are like MD calculations, but instead of proceeding along a time course, the system follows a random walk through configuration space [83]. Huge numbers of more or less randomly chosen Cartesian coordinates of the atoms of the system are considered. An ensemble average of the computed energies is used to calculate thermodynamic properties via statistical mechanics.

4.6. Statistical Modeling

By performing regression analysis and other statistical techniques, it is possible to quantitate the relation between molecular descriptors and an observed molecular property for a related set of compounds. The molecular property can be, for instance, the wavelength of an electronic transition, bioactivity, boiling point, chemical stability, etc. Descriptors can be almost

any quantity (— calculated or experimental —) that helps describe a molecule, such as molecular weight, atom counts, bond topological indices [84], molecular shape [85], or lipophilicity [14]. Descriptors related to substituents on an aromatic or aliphatic template have been assembled into large collections [86]. If a quantitative structure – property relationship (QSPR) can be found, then it can be used to predict (preferably by interpolation) the property of new structures. With the proliferation of descriptors, machine-learning techniques (see, e.g., [87]) have been developed to help choose the best ones [88].

4.7. Homology Modeling

Because of advances in the human genome project and in molecular biology in general, amino acid sequences of proteins are becoming known experimentally at a high rate, tens of thousands per year. Unfortunately, structural chemists cannot solve the 3D structures of these at the same rate, and it is very difficult to predict reliably how an amino acid sequence will fold.

One approach to obtaining a new 3D structure of a protein is to use homology modeling [89 – 92]. Here, the 3D structure has to be known for a sequence homologous to the new protein. The new sequence is threaded onto the backbone of the known structure, taking into account insertions and deletions in the sequence. The new model is then refined by energy minimization and an MD technique called simulated annealing. Thereby the theoretical temperature of the protein (determined by the kinetic energy of the atoms in the system) is gradually lowered in the hope that the structure will settle into a low minimum on the potential energy surface.

4.8. Drug Design Modeling

Some uses of the above methods have already been mentioned in regard to computer-aided drug design. In addition, a panoply of methods has been created specifically for applying molecular modeling to the design of chemical structures of interest to the pharmaceutical industry [93 – 98]. The vast majority of medicines perform their effect by binding to an enzyme or other protein. The rest target nucleic acids or other natural chemicals in the human body. Generally, synthetic molecules that bind to a biomacromolecule are called ligands.

Software tools [99, 100] have been developed to convert 2D chemical structures (as typically found in corporate and commercial databases) to 3D for further analysis by molecular modeling. Proprietary and commercial 3D databases are used by computational chemists in the pharmaceutical industry to search for structures matching a pharmacophore (the smallest set of atoms in a specific geometrical arrangement that will allow a molecule to be recognized by a biological receptor and bind to it). If appropriate hits from a 3D search are obtained, samples of the compounds can be submitted for testing in biological screens.

By combining quantitative structure – activity relationships (QSAR) and database tools, molecular modeling comes into play as a way to measure and maximize structural diversity in selecting compounds from databases for screening or to focus new compound libraries around a known lead structure. The ability of molecular modeling to provide molecular descriptors is important in database mining [101, 102] and combinatorial chemistry [103].

Comparative molecular field analysis (CoMFA) is a QSAR method that was developed in an attempt to model how ligands may be perceived in 3D by a receptor [104, 105]. The nonbonded van der Waals and electrostatic energies of a probe atom interacting at grid points surrounding a set of ligands are used as descriptors. The resulting data set has far more columns (descriptors) than rows (compounds). This situation is handled by the statistical method of partial least squares (PLS) of latent variables. If the ligands can be aligned in a strictly comparable way, then CoMFA can sometimes reveal which spatial regions surrounding a set of ligands enhance a property and which detract from it.

Some software tools combine conformational analysis and statistical modeling. These programs are designed to analyze the shapes of a series of compounds that are known to bind to the same receptor [106]. The algorithm tries to find conformations that let the more active compounds present a pharmacophore that the less active ones cannot. A statistical relationship is sought between activity and features in

the molecules, such as hydrophobic regions, hydrogen bonding sites, and ionized acidic or basic groups with formal positive or negative charge.

The 3D structure of many drug targets has not been determined. In such cases, methods for QSAR and modeling known ligands can be employed to elucidate the requirements for biological activity. In an increasing number of cases, a 3D structure of the drug target is known from experiment or can be built by molecular modeling. With a 3D structure in hand (structure-based drug design, SBDD), ligands can be docked in the receptor site [107 – 110]. Visual inspection of the docked molecules may reveal where adding or subtracting atoms/groups to/from the ligands would increase binding affinity. Usually, the better a drug binds to its intended target, the lower the required dose, and hence the lower the risk of side effects. The process of estimating the binding affinity is called scoring. A ligand may be able to orient in more than one way in a receptor; each orientation is called a pose. Computers may be used to automate the process in docking and scoring; this is called virtual screening [111].

A 3D model of a receptor can be further exploited with de novo design modeling programs [112, 113]. These programs generally have a library of molecular fragments, such as peptides or organic subunits, which they automatically assemble into possible 3D ligands. The hypothetical structures are evaluated in terms of the computed energy of interaction with the target receptor or other means. A weakness of early de novo design efforts was that they assumed that the target receptor structure is frozen. However, it is known both experimentally and computationally that some receptor sites change shape significantly when a ligand binds. Moreover, X-ray crystallography on ligand – receptor complexes shows that even similar ligands can occupy the receptor in different ways. Nevertheless, the de novo programs may suggest designs not previously considered, which can be followed up if they are synthetically feasible.

Pharmaceutical and biopharmaceutical companies currently use synthetic strategies, collectively called combinatorial chemistry, to produce thousands of compounds for biological screening. These sets of compounds are called libraries. Molecular modeling techniques are employed to increase the likelihood that bioactive compounds will be in the libraries [114, 115].

Genetic algorithms (GA) is a computational technique for solving optimization problems [116, 117]. The properties or constituents of a ligand can be modeled mathematically by a string of binary bits. Algorithms recombine and mutate these bit strings and then measure the resulting predicted property until the optimum combination of bits is found. GA can be used, for instance, to optimize the substituents on a molecular framework to fill a receptor cavity.

Computational drug design is extending beyond simply designing new ligands. Some of the new directions include studying the absorption, distribution, metabolism, and elimination (ADME) properties of compounds being considered for pharmaceutical development [118 – 121]. In addition, modeling is done to study potential toxicity of compounds. The preferred route of administration for most medicines is by mouth. Molecular modeling is used to study oral bioavailability [122]. One of the characteristics a compound must have to become a medicine is sufficient stability. Even this property is being scrutinized with molecular modeling [123].

The new field of cheminformatics is evolving mainly in regard to drug design as applied in industry [124, 125]. Cheminformatics arises from the cross-pollination of computer science, information science, and computational chemistry.

5. Economic Aspects

Most of the applications of molecular modeling alluded to in this article have dealt with compounds of interest to the pharmaceutical industry. This is because this area has to date been the largest area of applicability of the techniques. The total economic impact of molecular modeling is unknown, but the impact can be partially appreciated from the following data for the pharmaceutical industry. The major pharmaceutical companies operating in the United States, for instance, invested steadily greater amounts of their income in research and development: $\$ 2 \times 10^9$ in 1980, $\$ 15.2 \times 10^9$ in 1995, and $\$ 39.4 \times 10^9$ in 2005. Much of the money goes for clinical testing, and only a very tiny fraction is invested in modeling. Because the number of new drugs

Figure 4. Examples of drugs discovered with some help of computer modeling: dorzolamide (Trusopt), an agent for treating glaucoma; zolmitriptan (Zomig), a serotonin-1D agonist; donepezil (Aricept), an acetylcholinesterase inhibitor; ritonavir (Norvir) and nelfinavir (Viracept), both HIV protease inhibitors.

reaching the market has been relatively flat (due to scientific difficulty and regulatory factors), it is not surprising that the average cost of discovering and developing a new pharmaceutical product is huge and has grown from \$ 597×10^6 in 1994 to about \$ 10^9 ten years later. Almost the entire burden of the R& D costs must be born by sales of existing pharmaceuticals. The incentive to innovate and discover new and better medicines is made possible by the high cost of prescription drugs. Innovative medicines save lives, improve the quality of lives, and in general help the economy of a nation by increasing productivity.

A large company may spend \$ 10×10^6 per year to support molecular modeling; this amount includes the investment in the computational chemists and computer support staff, the cost of new computers to stay current with technology, the purchase of new software and databases, and the licenses to maintain existing software and databases. However, a small company can launch an entry-level molecular modeling effort for under \$ 50 000.

Because of the extreme difficulty of finding viable new pharmaceutical products, researchers must use every effective technology to help them discover the few new compounds that meet medical and market needs. Molecular modeling has proven to be one such technology. Rarely, if ever, can it be claimed that a marketed product was designed purely by molecular modeling. Usually modeling plays a supportive role to the other scientific disciplines of a research organization. Sometimes modeling supplies information that answers specific research questions. Sometimes modeling can nudge a project in a direction that eventually leads to a new product. Cases of the discovery of marketed pharmaceuticals which were influenced or assisted by some type of computer modeling have been documented [126 – 135]. Structure-based drug design efforts have been particularly productive [136]. The chemical structures of some of these compounds are shown in Figure 4. In addition, modeling has proved useful for finding marketed agrochemicals, such as those depicted in Figure 5 [137 – 139].

Figure 5. Examples of agrochemicals supported by computer modeling: bromobutide, a herbicide; metamitron, a photosystem II herbicide; myclobutanil (Systhane, Rally), a cytochrome P450 oxidase inhibitor.

Molecular modeling applications extend well beyond the pharmaceutical and agrochemical industries. Today, the methods are being used in industries commercializing adhesives, carbohydrates, catalysts, chromatographic stationary phases, clays [140], cleansing agents, corrosion inhibitors, crystals [141], explosives, flavorants, food components, fullerenes [142], glasses [143], hair colorings, lubricants and other petroleum products, materials [144], nanomaterials [145], nonlinear optical materials [146], nutrients, paint pigments, pesticides [147], photographic dyes, polymers, polysaccharides, semiconductors, soils [148], surfactants, water [149, 150], zeolites [151], and a host of other interesting materials (see, e.g., [152]). Uses of molecular modeling continue to grow because the computer methodologies help researchers gain a better appreciation of substances at a fundamental level.

Abstract

The article contains sections titled:

1. Physical and Chemical Properties
2. Production
3. Uses
4. Alkylnaphthalenes
5. Hydronaphthalenes
6. Economic Aspects
7. Toxicology

[Top of Page]

Naphthalene was discovered in coal tar by A. GARDEN in 1819.

[Top of Page]

1. Physical and Chemical Properties

Gerd Collin

Naphthalene [91-20-3], $C_{10}H_8$, M_r 128.18, *mp* 80.29 °C, *bp* 217.95 °C (101.3 kPa), forms colorless flakes or monoclinic crystals with a characteristic odor. It is readily soluble in benzene, diethyl ether, chloroform and carbon disulfide, soluble in ethanol, and insoluble in water. Naphthalene is volatile in steam and readily sublimable. It forms azeotropic mixtures with, for example, ethylene glycol, acetamide, *m*-cresol, and benzyl alcohol. Some important physical properties are as follows:

Density (20 °C)	1.1789 g/cm^3
Refractive index (99.5 °C)	1.5829
Heat capacity (25 °C)	1.294 kJ/kg
Heat of fusion	148 kJ/kg
Heat of vaporization	352 kJ/kg
Vapor pressure at 70 °C	0.525 kPa
at 88 °C	1.33 kPa
at 181 °C	40 kPa
at 270 °C	295 kPa
at 349 °C	1.01 MPa
at 479 °C	4.13 MPa
Critical temperature	475 °C
Flash point (closed cup)	80 °C

Ignition temperature	540 °C
Explosion limits in air	
upper	5.9 vol %
lower	0.88 vol %
Dielectric constant (20 °C)	2.47
Odor threshold	0.004 mg/m^3

Naphthalene can be catalytically hydrogenated in the liquid phase, preferably in the presence of nickel, with high selectivity to give tetra- and decahydronaphthalene, and in the gas phase in the presence of oxidic catalysts less selectively to give mixtures of tetra-, hexa-, octa-, and decahydronaphthalene. Liquid-phase oxidation with various oxidants or gas-phase oxidation with air in the presence of vanadium pentoxide catalysts gives (via 1,4-naphthoquinone) phthalic acid, which is readily dehydrated to phthalic anhydride (⟶ Phthalic Acid and Derivatives). The 1-position of naphthalene is the most nucleophilic. Consequently, electrophilic substitution reactions, such as nitration, halogenation, sulfonation, and alkylation at lower temperature, preferentially give the corresponding 1-substituted products; at higher temperature, isomerization occurs to give the thermodynamically more stable 2-substituted products. Nitration with nitric acid at low temperature produces 1-nitronaphthalene, and with H_2SO_4– HNO_3 at high temperature, 1,5- and 1,8-dinitronaphthalene (⟶). Halogenation forms 1-halo- and/or 1,4- and 1,5-dihalonaphthalenes, depending on the reaction conditions. Polychloronaphthalenes are obtained by catalytic chlorination at higher temperature (⟶ Chlorinated Hydrocarbons). Sulfonation with concentrated sulfuric acid gives 1-naphthalenesulfonic acid, and at higher temperature, 2-naphthalenesulfonic acid; oleum gives 1,5-, 1,6-, and 2,7-naphthalenedisulfonic acids and trisulfonic acids, depending on the SO_3 content (⟶). Naphthalene can be alkylated at higher temperature with alkyl halides, alcohols, and olefins in the presence of strong acids or Friedel-Crafts catalysts, with preferential formation of 2-alkyl derivatives (⟶ Acylation and Alkylation). Dehydrogenating condensation of naphthalene (Scholl reaction) gives perylene [198-55-0]. Acylation of naphthalene leads to mixtures of the 1- and 2-acyl derivatives, with the ratio depending on the solvent used (⟶ Acylation and Alkylation – Acylation of Polynuclear Aromatic Compounds). 1-Chloromethylation with paraformaldehyde and hydrochloric acid affords 1-chloromethylnaphthalene.

[Top of Page]

2. Production

Gerd Collin

The main feedstock for naphthalene production is coal tar. At an average content of around 10 %, naphthalene represents the most important compound in high-temperature coal tar (coke-oven tar) in terms of quantity. It can already be concentrated to over 90 % in primary tar distillation, in the naphthalene fraction boiling between 210 and 220 °C, with a yield in excess of 90 %. Further refining requires separation of the co-boiling compounds (phenols, nitrogen bases, benzo[*b*] thiophene, and other aromatic hydrocarbons). For production of technical naphthalene (e.g., *mp* 78.5 °C), redistillation of the naphthalene fraction is sufficient. Generally, phenols are extracted with sodium hydroxide solution before distillation (Fig. 1). Pure naphthalene (*mp* ≥79.6 °C) is produced by, e.g., crystallization or hydrorefining.

Figure 1. Naphthalene recovery from coal tar by extraction and distillation

a) Dephenolated naphthalene fraction; b) Dewatering column; c) Light oil column; d) Naphthalene column; e) Cooling; f) To the vacuum unit

Crystallization especially separates benzo[*b*]-thiophene, which boils at only 2 °C above naphthalene. Benzo[*b*]thiophene forms a eutectic mixture with naphthalene at a benzo[*b*]thiophene content of 93 %, and mixed crystals elsewhere in the phase diagram. Whereas until recently, naphthalene was predominantly recovered by crystallization from the melt, with formation of suspensions, newer processes of crystallization from the melt result in the formation of layers or blocks. Benzo [*b*]thiophene and other impurities can be separated from naphthalene by multistage countercurrent crystallization from the melt without adding selective solvents. Four to six crystallization stages are needed to produce pure naphthalene with a melting point of 80 °C from a coal tar primary fraction containing 90 % naphthalene.

Hydrorefining of naphthalene is carried out at 400 °C and ca. 1.4 MPa in the presence of cobalt – molybdenum catalysts, whereby benzo[*b*]-thiophene is converted to hydrogen sulfide and ethylbenzene. Other co-boiling compounds are broken down to lower-boiling hydrocarbons and can be separated by distillation. Naphthalene produced by this method has a sulfur content of ≤100 ppm and contains tetralin as the main by-product (ca. 1 %).

Other possible methods for separating benzo[*b*]thiophene include selective sulfonation, polycondensation with formaldehyde and acid, reaction with sodium metal, and azeotropic distillation with glycols.

Naphthalene can also be recovered from pyrolysis residue oils (from the pyrolysis of hydrocarbon fractions to olefins) by distillation and crystallization, in a manner similar to the recovery from coal tar. These pyrolysis residue oils normally contain 10 – 16 % naphthalene [6].

In addition to recovery from coal tar, naphthalene is also produced in the United States by hydrodealkylation of aromatized petroleum-derived fractions (Fig. 2) [7], [8]. Typical feedstocks are residue oils from catalytic naphtha reforming, from naphtha pyrolysis in olefin plants, or catcracker recycle oils. These aromatized oils are distilled to give a fraction containing naphthalene and alkylnaphthalenes and, in the case of catcracker recycle oils, subjected to extraction of the aromatics. The

bicyclic aromatic fraction, with a boiling range of, e.g., 220 – 270 °C, is dealkylated under hydrogen pressure, either thermally above 700 °C, or catalytically in the presence of a chromium oxide/aluminum oxide or cobalt oxide/molybdenum oxide catalyst at 550 – 650 °C. Methyl- and dimethylnaphthalene fractions from coal tar can also be hydrodealkylated. The crude dealkylation product is processed to a low-sulfur pure naphthalene (*mp* 80 °C) by distillation.

3. Uses

Gerd Collin

Worldwide, the main derivative of naphthalene is still phthalic anhydride (from catalytic gas-phase oxidation of naphthalene), an intermediate for PVC plasticizers (⟶ Phthalic Acid and Derivatives). Other important applications for naphthalene are dyes, particularly azo dyes produced from 2-naphthol [135-19-3] and naphthalene sulfonic acids (⟶ Azo Dyes). Naphthalene and alkylnaphthalene sulfonates are used as surfactants, and naphthalene sulfonate – formaldehyde condensates as tanning agents (syntans) and dispersants, e.g., as superplasticizers for concrete (⟶ Disperse Systems and Dispersants – Formaldehyde Condensation Products). Naphthalene is used in the production of moth repellents and fumigants and the insecticide carbaryl (1-naphthyl-*N*-methylcarbamate). It is also used for the synthesis of tetrahydroanthraquinone from naphthoquinone and butadiene (⟶ Anthraquinone – Production) and for alkylnaphthalene solvents for carbonless copy paper (Kureha Micro Capsule Oil, KMC, a mixture of diisopropylnaphthalene isomers), the solvents tetralin and decalin, as well as chlorinated naphthalenes (⟶ Chlorinated Hydrocarbons), of which only the monochloronaphthalenes retain commercial significance, e.g., as dye dispersants and as fungicides and insecticides for preservatives. Polychlorinated naphthalenes are rarely produced due to their toxicity and resistance to environmental degradation. 1-Methyl- and 1-chloromethylnaphthalene are used in the production of the plant growth regulators 1-naphthaleneacetamide [86-86-2] and 1-naphthaleneacetic acid [86-87-3]. The alkaline-earth salts of sulfonated dinonylnaphthalenes are important lube-oil additives. New applications are opening up for 2,6-naphthalenedicarboxylic acid and 6-hydroxy-2-naphthoic acid as intermediates for liquid crystal polymers and heat-resistant polyester fibers and films. For further details on the uses of naphthalene, see Figure 3.

Figure 3. Uses of naphthalene

[Top of Page]

4. Alkylnaphthalenes

Gerd Collin

1-Methylnaphthalene [90-12-0], $C_{11}H_{10}$, M_r 142.20, *bp* 244.4 °C (101.3 kPa), *mp* –30.5 °C, d^{20} 1.0203, is a colorless, blue-fluorescing liquid which is readily soluble in benzene, ethanol, and diethyl ether, and insoluble in water. 1-Methylnaphthalene is present in high-temperature coal tar in a concentration of 0.5 % and is produced industrially from the methylnaphthalene fraction, which boils between 240 and 245 °C, by redistillation of the 2-methylnaphthalene filtrate following crystallization and separation of 2-methylnaphthalene. 1-Methylnaphthalene can be isomerized to 2-methylnaphthalene in the presence of, e.g., BF_3, phosphoric acid, and phase-transfer catalysts [9], or on zeolite catalysts [10]. It is used for the synthesis of 1-naphthaleneacetic acid and, in mixtures with 2-methylnaphthalene, as a solvent and heattransfer oil.

2-Methylnaphthalene [91-57-6], $C_{11}H_{10}$, M_r 142.20, *bp* 241.1 °C (101.3 kPa), *mp* 34.6 °C, d^{20} 1.029, forms colorless crystals. The compound is readily soluble in benzene, ethanol and carbon disulfide, but insoluble in water. It is recovered industrially by crystallization from the methylnaphthalene fraction of high-temperature coal tar, which contains 1.5 % 2-methylnaphthalene. 2-Methylnaphthalene can also be produced by isomerization of 1-methylnaphthalene (see above). 2-Methylnaphthalene is the feedstock for the production of 2-methyl-1,4-naphthoquinone [58-27-5] (menadione, vitamin K_3), and mixtures with 1-methylnaphthalene are used as solvents and heat-transfer oils. It is used in small quantities for the production of alkylmethylnaphthalene sulfonates as textile auxiliaries, surfactants, and emulsifiers. 2-Methylnaphthalene can be used via 2-methyl-6-acetylnaphthalene [11], [12], or in an older process (also as a mixture with 1-methylnaphthalene) by oxidation with subsequent Henkel rearrangement, to give 2,6-naphthalenedicarboxylic acid [1141-38-4] (⟶ Carboxylic Acids, Aromatic). This compound is used in the production of special heat-resistant polyester fibers and films, and of liquid crystal polymers. 2-Methylnaphthalene can be acylated in 1,2-dichlorbenzene to give 1-acyl-7-methylnaphthalene [13], which can be used as an intermediate for pharmaceuticals [14].

2,6-Dimethylnaphthalene [581-42-0], $C_{12}H_{12}$, M_r 156.23, *bp* 261 °C (101.3 kPa), *mp* 110 °C, forms colorless crystals which are slightly soluble in ethanol and insoluble in water. It can be recovered from the dimethylnaphthalene fraction of coal tar by redistillation and crystallization; from aromatized catcracker recycle oil by aromatics extraction, redistillation, hydrogenation of the isomer mixture to dimethyltetralins, isomerization, and dehydrogenation; or by disproportionation of methylnaphthalenes to give naphthalene and dimethylnaphthalenes, from which the 2,6-isomer can be obtained analogously to the production from aromatized catcracker recycle oil. 2,6-Dimethylnaphthalene is also obtained by alkylation of 2-methylnaphthalene or naphthalene on zeolite catalysts [15], [16].

2,6-Dimethylnaphthalene can be converted to 2,6-naphthalene dicarboxylic acid by liquid-phase oxidation with oxygen in acetic acid as solvent in the presence of a cobalt acetate/manganese bromide catalyst and a co-catalyst, e.g., ruthenium chloride [17].

2-Isopropylnaphthalene [2027-17-0], $C_{13}H_{14}$, M_r 170.25, *bp* 268.9 °C (101.3 kPa), *mp* 15.1 °C, d^{20} 0.9762, is a colorless liquid. It can be used to synthesize 1-naphthol [90-15-3] by oxidation via the hydroperoxide (Hock synthesis) (⟶). Catalytic gas-phase dehydrogenation produces polymerizable 2-isopropenylnaphthalene [3710-23-4] [18].

Diisopropylnaphthalenes. Selective Friedel-Crafts alkylation of naphthalene with propene in the presence of an aluminum silicate catalyst yields as the main product a mixture of diisopropylnaphthalene isomers that is liquid over a wide temperature range. This isomer mixture is used as a solvent for carbonless copy paper [19], [20]. The solvent, trade name KMC (Kureha Micro Capsule Oil), is odorless, colorless, and environmentally harmless [21]. KMC can also be used as a solvent for scintillation measurements and as a heat transfer oil. Some physical properties of KMC are as follows:

Boiling range (101.3 kPa)	290 – 299 °C
Pour point	<–40 °C
Flash point	>130 °C
Density (15 °C)	0.96 g/cm^3
Refractive index (25 °C)	1.565
Specific heat (20 °C)	1.71 kJ/kg K
Thermal conductivity (20 °C)	0.12 W/Km
Dielectric constant (90 °C)	2.46

Technically pure *2,6-diisopropylnaphthalene* [24157-81-1] (*mp* 70 °C) can be isolated from the isomer mixture by crystallization [22]. It can be converted to 2,6-naphthalene dicarboxylic acid [23-25] or to 6-hydroxy-2-naphthoic acid [16712-64-4] by liquid-phase oxidation [26]. These compounds are used as intermediates for heat-resistant liquid crystal polyesters [27].

5. Hydronaphthalenes

Gerd Collin

1,2,3,4-Tetrahydronaphthalene [119-64-2], tetralin, $C_{10}H_{12}$, M_r 132.21, *bp* 207.3 °C (101.3 kPa), *mp* –35 °C, d^{20} 0.9729, n_D^{20} 1.5461, is a colorless liquid which is infinitely soluble in chloroform, petroleum ether (ligroin), diethyl ether, and ethanol, but insoluble in water. Tetralin is produced industrially by selective hydrogenation of low-sulfur naphthalene in the presence of nickel catalysts at 180 – 260 °C and 1 – 1.5 MPa.

Tetralin is used as a solvent for fats, resins, and paints; for the production of detergents; and for the synthesis of carbaryl via 1-naphthol. It can be applied as a hydrogen-donor solvent in coal extraction (⟶ Coal Liquefaction – Solvents).

Decahydronaphthalene [91-17-8], decalin, $C_{10}H_{18}$, M_r 138.25, exists in two stereoisomeric forms: *trans*-decalin, *bp* 185.5 °C (101.3 kPa), *mp* –32.5 °C, d^{20} 0.8700 , n_D^{20} 1.4696; and *cis*-decalin, *bp* 195 °C, *mp* –45 °C (101.3 kPa), d^{20} 0.8967, n_D^{20} 1.4811.

The isomer mixture is a colorless liquid with a camphor-like odor. Technical decalin is infinitely soluble in butanol, soluble in chloroform, acetone, carbon disulfide and benzene, and slightly soluble in ethanol and methanol.

Decalin is produced by liquid-phase hydrogenation of naphthalene under pressure in the presence of nickel catalysts. The proportion of the two stereoisomers formed depends on the reaction conditions.

Like tetralin, decalin is used as a solvent for fats, resins, waxes, and paints. It can also be used to make cyclodecanone, an intermediate in the production of polyamide 10.

6. Economic Aspects

Gerd Collin

World production of naphthalene in 1987 was ca. 10^6 t. About one-fourth of this came from Western Europe, one-fifth each

from Japan and Eastern Europe, and one-eighth from the United States. In addition to coal-tar based naphthalene, petroleum-derived naphthalene has been recovered since 1961, predominantly in the United States, by dealkylation of aromatics-rich fractions from reforming and catalytic cracking. The proportion of petroleum-based naphthalene has decreased during the last decade from ca. 15 % to ca. 5 %, because coal-tar naphthalene is available in sufficient quantity. Table 1 summarizes the main uses of naphthalene as percentage of consumption in Western Europe, Japan, and the United States.

Table 1. Uses of naphthalene in % (1987)

Use	Western Europe	United States	Japan
Phthalic anhydride	40	65	70
Dyes	29		10
Surfactants, tanning agents, dispersants	15	14	5
Moth repellants, fumigants	9	5	2
Insecticides		14	
Solvents and other uses	7	2	12

An application for alkylnaphthalenes is the use of diisopropylnaphthalene isomer mixtures as solvents for carbonless copy paper. Production capacities for these mixtures, trade name KMC, total 10 000 t/a each in Japan and the Federal Republic of Germany. World production of 2-methylnaphthalene and 1-/2-methylnaphthalene mixtures is estimated at 1500 t/a each. For hydronaphthalenes, tetralin production is estimated to be 25 000 t/a worldwide. Naphthalenesulfonate – formaldehyde condensates are produced worldwide in quantities of ca. 40 000 t/a, predominantly for concrete plasticizers. Although polyester products derived from 2,6-naphthalenedicarboxylic acid or 6-hydroxy-2-naphthoic acid have been on the market for some time, they have not yet gained major commercial importance.

7. Toxicology

Hartmut Höke and Helmut Greim

Naphthalene

Human Health. The health consequences of human exposure to naphthalene have been repeatedly evaluated [48-51]. Most of the information given subsequently derives from these reports.

Effects assessment. Naphthalene is readily absorbed during oral, inhalation and dermal exposure. In rodents it is metabolized by epoxidation and subsequent hydroxylation. These reactive metabolites undergo glutathione conjugation or reduction forming the 1,2-dihydrodiol. In humans, 1-naphthol, 2-naphthol, and 1,2-, and 1,4-naphthoquinone are formed. More recent data demonstrate that cytochrome P450-2F2 in cellular systems of rats and mice metabolizes naphthalene to 1R,2S-naphthaleneoxide [52] which rearranges to 1-naphthol and forms the 1,2-dihydrodiol by hydrolase activity. Oxidation of 1-naphthol forms 1,2-, and 1,4-naphthoquinone [53]. In Clara cells isolated from the lungs of naphthalene treated mice ZHENG et al. [54] reported covalent binding of 1,2-naphthoquinone to protein.

In humans, single or repeated exposures to naphthalene caused severe hemolytic anemia esp. in infants exposed to textiles (clothing/bedding), which have been stored with naphthalene mothballs. It may cause slight irritation on contact with the skin and eyes. The absence of case reports indicates that naphthalene is not a skin or respiratory sensitizer in humans.

In rodents naphthalene is of low acute toxicity and did not show sensitizing activity. Repeated oral administration of naphthalene causes cataracts in rats and rabbits at doses of 700 mg/kg bw/d and above. Despite its widespread use there are no reliable reports of cataracts in humans. Repeated inhalation exposure for 28 days produces irritation of the nasal epithelium, with mild effects at levels as low as 5 mg/m^3 in rats (LOAEL). In mice, signs of chronic respiratory tract inflammation were noted at 50 mg/m^3. There was no indication of hemolytic anemia in rodent studies.

Naphthalene was not mutagenic in bacterial assays and did not induce UDS *in vitro*. In CHO cells clastogenic effects and sister chromatid exchanges (SCE) were found *in vitro* in the presence and in the absence of metabolic activation. In human peripheral lymphocytes no SCEs have been induced in the presence or absence of microsomal enzymes. Other *in vitro* tests (micronuclei in MCL-5 cells [55], DNA fragmentation in macrophages [56], chromosomal aberrations in mice embryo cultures [57, 58]) indicated genotoxic effects. *In vivo*, naphthalene did not induce micronuclei in bone marrow cells of mice or UDS in rat liver cells. The metabolic formation of an epoxide, which may also be formed in the nasal cavity of rats in the

carcinogenicity studies, implies that the involvement of a genotoxic mechanism in tumor formation at this target cannot be excluded.

In a carcinogenicity study [59] by inhalation, naphthalene produced epithelial adenomas and olfactory epithelial neuroblastomas in the nasal cavity of rats from the lowest exposure concentration (50 mg/m^3). This must be considered of high relevance because neuroblastomas are highly malignant and the P450 isozymes that metabolically activate naphthalene in the nasal cavity of rodents are also present in humans. In mice an increased incidence in pulmonary adenomas was seen. Since lung tumors were not seen in rats, and due to the higher capacity of the mouse lung in metabolic activation and inactivation, the pulmonary tumors seen in mice seem to be of little relevance to humans.

No studies to evaluate reproductive toxicity are available. Although no changes in the reproductive organs have been detected in repeated dose studies, appropriate studies are needed.

Exposure. Highest occupational exposures occur in mothball manufacture, from the manufacture of grinding wheels and the use of creosote.

Exposure via inhalation also occurs when organic material is incompletely combusted (e.g., in processing of coal, crude oil and natural gas, metal foundries, and power plants).

Consumer exposure to naphthalene may occur through the use of moth repellents, tar shampoos and soaps and through damp proofing operations.

Significant exposure in the mg/kg bw/d range was estimated from dermal and inhalation exposures for workers and consumers. Professional use of tar soap and shampoos exposure was considered to be low.

Indirect human exposure via the environment is low. Infants, in particular, may significantly be exposed to textiles (clothing/bedding), which have been in contact with naphthalene mothballs.

Human exposure via the environment is estimated to range from 65 ng/kg/d at the regional level to 0.25 mg/kg/d at the local level with releases from the manufacture of grinding wheels or mothballs contributing most. Environmental airborne levels are 0.14 µg/m^3.

Risk characterization. The available information indicates that there are no concerns regarding irritation, sensitization and mutagenicity.

The critical health effects are hemolytic anemia and carcinogenicity.

Since a NOAEL for hemolytic anemia cannot be established, there is concern due to exposure of neonates and infants to clothes that have been in contact with mothballs and following dump-proofing. The predicted exposures are high and can be close to concentrations at which local damage to the respiratory tract has occurred in rats.

In the carcinogenicity studies in rats, chronic inflammation may be a key mechanism in the development of the nasal tumors. However, it cannot be concluded whether a secondary genotoxicity due to chronic inflammation or a genotoxic effect is the relevant mechanisms of naphthalene to induce tumors. Formation of an epoxide and the clastogenic effects in vitro suggest involvement of a genotoxic mechanism.

1-Methylnaphthalene and 2-methylnaphthalene show only low toxicity; the oral LD_{50} values in rats were determined at 2800 and 3850 mg/kg, respectively [39]. At high oral doses in rats, acute symptoms are unspecific and indicate impairment of the nervous system and hemorrhagic edema of inner organs. After intraperitoneal injection into mice, epithelial necrosis of the lung was induced, morphologically similar to that found with naphthalene [40], [41]. Other specific phenomena that are characteristic of naphthalene exposure, i.e., hemolytic anemia and formation of cataracts, are unknown for methylnaphthalenes. In humans, no intoxications related to these aromatic compounds have been reported.

Diisopropylnaphthalenes (mixture of isomers, KMC) cause no toxic symptoms in rats up to high dosage levels: in the range from about 3.0 g/kg under acute conditions to 30 mg kg^{-1} d^{-1} in a long-term study for 24 months. There are generally involved unspecific, mostly reversible phenomena such as loss of body weight, digestive dysfunction, enlargement of the liver, and local disturbed circulation (hyperemia) [42]. In skin and eye irritation tests conducted on rabbits, diisopropylnapthtalenes exhibited slightly irritant, but reversible effects, which allows the product to be classified as nonirritant. Likewise, there is no evidence of sensitization [42]. No adverse effects were observed in a group of 80 workers who had had contact with diisopropylnapthalenes during production of carbonless copy paper [42]. Mutagenicity and carcinogenicity tests (24 months, oral, rat) gave no evidence of a carcinogenic potential, nor were teratogenic malformations found (mice, oral) [42]. Diisopropylnaphthalenes were rapidly released from the body, i.e., > 80 % within 15 h (mice) [42], and within 10 d (carp) [43], and they proved to be biodegradable [44].

Tetralin and decalin are irritant to the skin, eye, and to the mucous membranes on inhalation. They may cause nervous disturbances, headache, or numbness. The lowest concentration of decalin in air that exhibited an effect on humans was ca. 100 ppm; a 4 h exposure to 500 ppm was lethal to 4 from 6 rats [45]. In guinea pigs, morphological changes of the kidney, liver, and lung were observed after subacute inhalation of decalin [45]. Methemoglobinemia was induced by tetralin in cats; the same effect was found in infants after accidential exposure to tetralin [46]. The color of human urine may change to brownish green or green-gray after incorporation of decalin or tetralin [45]. Acute range finding studies revealed an oral LD_{50} (rat) of 4.17 g/kg for decalin and 2.68 g/kg for tetralin [45]. A TLV of 25 ppm has been suggested for decalin [47].

1. Introduction

Although the basis of naphthalene chemistry can be said to have started with ERLENMEYER in 1866, conclusive chemical evidence for the structure of naphthalene and its early derivatives (e.g., mono- and dinitroderivatives and α-naphthylamine) was published in 1888 by REVERDIN and NOELTING [5].

By 1900, hundreds of new naphthalene derivatives had been prepared as components for azo dyes. Not only was this early work, reported in German patents and journals, remarkably accurate in view of the comparatively primitive analytical techniques available, but the key compounds that emerged at that time remain dominant to this day. The trivial names given to these dye intermediates (Table 1) have also survived and are commonly used in the industry.

Table 1. Letter acids and other code-named naphthalene intermediates

A acid	3,5-dihydroxynaphthalene-2,7-disulfonic acid
Amino epsilon acid	1-aminonaphthalene-3,8-disulfonic acid
Amino F acid	2-aminonaphthalene-7-sulfonic acid
Amino G acid	2-aminonaphthalene-6,8-disulfonic acid
Amino J acid	2-aminonaphthalene-5,7-disulfonic acid
Amino R acid	2-aminonaphthalene-3,6-disulfonic acid
Armstrong acid	naphthalene-1,5-disulfonic acid
B acid	1-aminonaphthalene-4,6,8-trisulfonic acid
Badische acid	2-aminonaphthalene-8-sulfonic acid
BON acid	3-hydroxy-2-naphthoic acid
Böniger acid	1-amino-2-hydroxynaphthalene-4-sulfonic acid

T acid	1-aminonaphthalene-3,6,8-trisulfonic acid
Tobias acid	2-aminonaphthalene-1-sulfonic acid
Violet (RG) acid	1-hydroxynaphthalene-3,6-disulfonic acid

The important Armstrong – Wynne rules for polysubstitution of naphthalene and its derivatives by nitration and sulfonation were also formulated in this early period. Although empirical, they have stood the test of time against increasingly sophisticated theories and calculations.

Improved processes based on the key unit processes of sulfonation, nitration, reduction, hydroxylation, and amination (Bucherer reaction) for a wide range of naphthalene derivatives were developed during the next 40 years [6]. Although these were not published [7] until after 1945 with the end of the I.G. Farbenindustrie era, all the important subsequent reviews [5], [8–10] were based largely on these comprehensive data.

The only significant production development work published in the last 40 years is related to the project for the new Schelde-Chemie plant (Bayer Ciba-Geigy joint venture) designed to manufacture 14 000 t/a of naphthalene intermediates at Brunsbüttel [16]. The process development on important letter acids (H, J, γ, C, Peri, and Laurent's) required a major change from the traditional processes, optimized over 80 years, to meet present-day energy and environmental requirements [17].

Azo dyes and pigments continue to be major outlets for naphthalene intermediates (see also →Azo Dyes). The Colour Index lists some 270 different naphthalene intermediates as precursors to many more colorants [18]. This represents about 20 % of the total list of intermediates. Supplementary updating volumes list only seven new naphthalene intermediates and relatively few new outlets for existing intermediates [19]. From this one may infer that very little new colorant research is being carried out based on novel naphthalene derivatives. In contrast, other areas such as agrochemicals and pharmaceuticals have been most active in exploiting new naphthalene derivatives over the last 20 years [11].

2. Naphthalenesulfonic Acids

2.1. Production and Properties

Controlled sulfonation using a range of sulfuric acid and oleum strengths under a variety of reaction conditions leads to formation of mono-, di-, tri-, and tetrasulfonic acids, whose separation is frequently complicated by desulfonation (i.e., reverse sulfonation) or isomerization.

Table 2. Salts of key naphthalenesulfonic acids

Salt	Hydrate	Solubility, g in 100 mL H_2O
1-Sulfonic acid		
Sodium	1/2 H_2O	9.1 (10 °C)
Potassium	1/2 H_2O	7.7 (10 °C)
Calcium	2 H_2O	6.1 (10 °C)
Barium	1 H_2O	1.2 (10 °C)
2-Sulfonic acid		
Sodium		5.9 (25 °C)
Potassium	1/2 H_2O	6.7 (10 °C)
Calcium	1 H_2O	1.3 (10 °C)
Barium	1 H_2O	0.35 (10 °C)
1,5-Disulfonic acid		
Sodium	2 H_2O	11.1 (18 °C)
Potassium	2 H_2O	6.7 (18 °C)
Calcium	2 H_2O	2.5 (18 °C)
Barium	1 H_2O	0.21 (18 °C)
1,6-Disulfonic acid		
Sodium	7 H_2O	33.3 (18 °C)
Potassium		20.0 (18 °C)
Calcium	4 H_2O	10.0 (18 °C)
Barium	31/2 H_2O	6.2 (100 °C)
2,6-Disulfonic acid		
Sodium	1 H_2O	11.9 (18 °C)
Potassium		5.2 (18 °C)
Calcium		6.2 (18 °C)
Barium	1 H_2O	<0.1
2,7-Disulfonic acid		
Sodium	6 H_2O	45 (18 °C)
Potassium	2 H_2O	71 (18 °C)
Calcium	6 H_2O	16 (18 °C)
Barium	2 H_2O	1.2 (19 °C)

A common method for isolating naphthalenesulfonic acids and substituted derivatives obtained by sulfonation is the liming-out process. This consists of neutralizing the quenched sulfonation mass (i.e., after addition to excess water) with lime and filtering off the precipitated calcium sulfate while still hot. The solution of the calcium salt of the product is then titrated with sodium carbonate to form the sodium salt. Precipitated calcium carbonate is removed by filtration, and the solution is either evaporated to give the solid sodium salt or used to precipitate a less soluble salt. This technique may be employed in the laboratory to give pure products by using barium instead of calcium, provided the barium salt of the product has sufficient solubility in hot water.

The twelve sulfonated products most readily obtained from naphthalene are shown in Figure 1.

Separation of naphthalenesulfonic acids and downstream derivatives for analysis may be accomplished on small-scale columns by ion-exchange [20], ion-pair [21], or high-performance liquid [17] chromatography.

The naphthalenesulfonic acids are all extremely water soluble and are strong acids in solution. Alkali-metal and alkaline-earth salts are also water soluble but with a progression toward sparingly soluble barium salts, as shown in Table 2. The moderately soluble salts are readily precipitated from the mineral acid solution, with variations in crystal form according to conditions.

Naphthalene-2-sulfonic acid is isolated for conversion to 2-naphthol, but the sulfonation mass is further sulfonated in situ for the production of di- and trisulfonic acids. Naphthalene-1-sulfonic acid is not usually isolated on a large scale because 1-naphthol is produced advantageously by other routes. The 1-isomer is, however, nitrated in situ for the manufacture of Peri and Laurent's acids (see Chap. 6).

Naphthalenedisulfonic acids are converted into naphthol sulfonic acids (Chap. 4) and dihydroxynaphthalenes (Section 3.3), or are nitrated to form intermediates for aminonaphthalenedisulfonic acids and aminonaphtholsulfonic acids (Chap. 8). Naphthalenetrisulfonic acids similarly afford aminohydroxynaphthalenedisulfonic acids (e.g., H acid). The one readily accessible naphthalenetetrasulfonic acid has no large-scale application.

2.2. Monosulfonic Acids

Naphthalene-1-sulfonic acid [*85-47-2*] (**1**), naphthalene-α-sulfonic acid, $C_{10}H_8O_3S$, M_r 208.23, crystallizes from aqueous solutions as the dihydrate, *mp* 90 °C; dehydration (P_2O_5, 1.33 kPa) gives the anhydrous acid, *mp* 139 – 140 °C. Aqueous solubilities of the alkali-metal salts are given in Table 2.

Naphthalene-1-sulfonic acid is desulfonated to naphthalene by heating with dilute mineral acid. Halogenation also removes the sulfonic acid group, mainly with formation of 1,5-dihalonaphthalenes. Naphthalene-1-sulfonyl chloride, *mp* 68 °C, is prepared by treatment of the anhydrous acid with phosphorus pentachloride at 100 °C.

Production. Naphthalene-1-sulfonic acid is produced by adding naphthalene to 96 % sul-

Figure 1. Sulfonation of naphthalene

furic acid at 20 °C and slowly raising the temperature to 70 °C [7]. After 3 h at 70 – 75 °C the reaction mass is poured into water and limed out. A technical-grade product is obtained by evaporation and a purer product by precipitating the aniline salt.

An alternative sulfonation process uses sulfur trioxide in a solvent such as tetrachloroethane.

Uses. Naphthalene-1-sulfonic acid is further sulfonated or nitrated without isolation. At lower temperature (35 °C), sulfuric acid with oleum yields the 1,5-disulfonic acid, whereas at higher temperature (100 °C) the 1,6-disulfonic acid is predominantly obtained. Nitration gives mainly the 5-nitro and 8-nitro derivatives (see Section 6.1). Production of 1-naphthol by caustic fusion (hydroxylation) has long since been superseded by alternatives for reasons of product quality (Section 3.1).

Naphthalene-2-sulfonic acid [*120-18-3*] (**2**), naphthalene-β-sulfonic acid, $C_{10}H_8O_3S$, M_r 208.23, crystallizes from aqueous solutions as the hydrate (*mp* 124 °C) or trihydrate (*mp* 83 °C). Aqueous solubilities of the free acid and its salts are somewhat lower than those of the corresponding α-isomers (Table 2). The isolated sodium salt is known as β salt.

Naphthalene-2-sulfonic acid is desulfonated by hot aqueous mineral acids with much more difficulty than naphthalene-1-sulfonic acid; the rate has been measured at 50 times slower [22]. Halogenation attacks either or both the 5- and the 8-positions. Bromination may be used to separate a mixture of naphthalene-1-sulfonic acid from naphthalene-2-sulfonic acid because the latter forms a soluble product whereas the former is desulfonated.

Production. Molten naphthalene is added to 96 % sulfuric acid in an iron vessel and the mixture is agitated at 163 °C for 2 h. A complex

work-up consisting of gradual dilution, heating, and neutralization with caustic soda and sodium sulfite ensures an 88 % yield of isolated β salt and desulfonation of the α-isomer, which is formed as a coproduct in 5 – 10 % yield [7].

Uses. The major outlet for β salt is the production of 2-naphthol (Section 3.2). The 2-sulfonic acid is a stage in the production of the 1,6-, 2,6-, and 2,7-disulfonic acids and the 1,3,6-trisulfonic acid. Nitration gives primarily the 5- and 8-nitro derivatives as intermediates for Cleve's acids (Section 6.1). The 2-sulfonic acid condenses with formaldehyde or alcohols to form surface-active agents (see Section 2.5).

The intermediate 2-thionaphthol can be obtained by catalytic hydrogenation of naphthalene-2-sulfonic acid, but is traditionally made by zinc reduction of naphthalene-2-sulfonyl chloride.

2.3. Disulfonic Acids

Naphthalene-1,3-disulfonic acid
[*6094-26-4*] (**3**), $C_{10}H_8O_6S_2$, M_r 288.28, is produced only in small proportion on disulfonation of naphthalene and cannot be separated. It is prepared in good yield in the laboratory by diazotization and copper-catalyzed deamination of 2-aminonaphthalene-6,8-disulfonic acid [23].

Naphthalene-1,5-disulfonic acid
[*81-04-9*] (**4**), Armstrong acid, $C_{10}H_8O_6S_2$, M_r 288.28, crystallizes as the tetrahydrate but dehydrates at 125 °C to give the anhydrous acid (*mp* 240 – 245 °C). Solubilities of the alkali-metal salts are given in Table 2.

The disulfonic acid forms an anhydride when treated with oleum below 50 °C. This anhydride reacts with ammonia to give a mixture of naphthalene-1,5-disulfonamide and naphthalene-1-sulfonamide-5-sulfonic acid. Treatment of the disodium salt of naphthalene-1,5-disulfonic acid with phosphorus pentachloride at 110 °C gives naphthalene-1,5-disulfonyl chloride (*mp* 184 °C), which may also be prepared by chlorosulfonation of naphthalene. Reaction of an aqueous solution of naphthalene-1,5-disulfonic acid with bromide – bromate gives 1,5-dibromonaphthalene so readily that the yellow precipitate may be used to identify very low concentrations of the disulfonic acid.

Production. Naphthalene is mixed with 20 % oleum at 20 – 35 °C followed by gradual addition of 65 % oleum and further naphthalene alternately. After heating for 6 h at 55 °C the reaction mixture is added to water, and the product is precipitated as the free acid by cooling or as the disodium salt by the addition of alkaline sodium sulfate. In each case, the isolated yield is ca. 53 %. The 1,6-disulfonic acid can be recovered from the filtrate.

Higher yields of **4** have been reported for alternative processes; for example, solvent sulfonation with sulfur trioxide and chlorosulfonic acid in a solvent such as tetrachloroethylene [24] or sulfonation with oleum through a double screw-feed apparatus [25].

Uses. The disodium salt of naphthalene-1,5-disulfonic acid gives 1-hydroxynaphthalene-5-sulfonic acid or 1,5-dihydroxynaphthalene (see Section 3.3) by fusion processes. Further sulfonation of the disulfonated reaction mixture gives naphthalene-1,3,5-trisulfonic acid (**9**), and nitration leads to 1- and 2-nitronaphthalene-4,8-disulfonic acids as intermediates to the corresponding aminonaphthalene disulfonic acids (Chap. 6).

Naphthalene-1,5-disulfonic acid is an important stabilizer for diazo compounds [26].

Naphthalene-1,6-disulfonic acid
[*525-37-1*] (**5**), $C_{10}H_8O_6S_2$, M_r 288.28, crystallizes as the tetrahydrate, *mp* 125 °C (decomp.). Solubilities of the alkali-metal salts are given in Table 2.

Production. Separation from the 1,5-disulfonic acid process (see above) usually meets requirements for the preparation of **5**. It can also be prepared by sulfonation of naphthalene-2-sulfonic acid with oleum, which gives naphthalene-1,7-disulfonic acid (**6**) as a byproduct [12].

Uses. Alkali fusion of **5** yields 1,6-dihydroxynaphthalene (Section 3.3), and sulfonation with oleum produces naphthalene-1,3,6-trisulfonic acid (**10**). However, the main outlet for naphthalene-1,6-disulfonic acid is via nitration to 1-nitronaphthalene-3,8-disulfonic acid, which is the intermediate for 1-aminonaphthalene-3,8-disulfonic acid (Section 6.4).

Naphthalene-1,7-disulfonic acid
[*5724-16-3*] (**6**), $C_{10}H_8O_6S_2$, M_r 288.28, is

produced by sulfonation of naphthalene-2-sulfonic acid (**2**) with cold oleum to give a mixture of 1,6- (80 %) and 1,7- (20 %) acids. Although these are difficult to separate, the corresponding disulfonyl chlorides are separable because of their differing solubilities in, for example, benzene.

Naphthalene-2,6-disulfonic acid [*581-75-9*] (**7**), $C_{10}H_8O_6S_2$, M_r 288.28, crystallizes as the dihydrate, *mp* 129 °C. The alkali-metal salts are much less soluble than those of the 2,7-isomer (Table 2).

Production. Naphthalene is added to sulfuric acid – monohydrate ($SO_3 \cdot H_2O$) mixture at 135 °C, and the reaction is completed by heating at 170 – 175 °C for 5 h. After quenching in water, the disodium salt of **7** is precipitated at 90 °C by adding sodium chloride and sodium sulfate. Filtration at 95 °C followed by washing with sodium sulfate solution gives the required product, free from the 2,7-isomer, in 21 % yield. The 2,7-isomer is then isolated from the filtrates.

Uses. The disodium salt of **7** gives 2-hydroxynaphthalene-6-sulfonic acid or 2,6-dihydroxynaphthalene (Section 3.3) by fusion processes. Nitration of the crude sulfonation product containing 2,6- and 2,7-disulfonic acids gives the 4-nitro derivatives, which, on reduction, give the mixed 1-aminonaphthalene-3,6(3,7)-disulfonic acid (Freund's acid).

Naphthalene-2,7-disulfonic acid [*92-41-1*] (**8**), $C_{10}H_8O_6S_2$, M_r 288.28; the sodium salt of **8** is much more soluble than that of the 2,6-isomer (Table 2) but can be isolated and purified by precipitation of the calcium salt at lower temperature followed by recrystallization.

Production. The 2,7-disulfonic acid is always the main product of high-temperature sulfonation of naphthalene, but at 160 °C it converts slowly to an equilibrium mixture containing ca. 30 % of the 2,6-isomer [12]. Crystallization of the pure product from conventional sulfonation is difficult, and alternative processes, (for example, reaction of naphthalene vapor with sulfur trioxide in the gas phase at 220 °C) are said to give a purer product.

Uses. The disodium salt of **8** gives 2-hydroxynaphthalene-7-sulfonic acid or 2,7-dihydroxynaphthalene (Section 3.3) by fusion processes. Sulfonation by oleum gives the 1,3,6-trisulfonic acid, and nitration gives 1-nitronaphthalene-3,6-disulfonic acid.

In sulfuric acid solution, the disodium salt of naphthalene-2,7-disulfonic acid undergoes an unusual reaction at the 4-position with 4,4′-bis-(dimethylamino)benzhydrol. The resulting condensation product is oxidized with lead dioxide to give the acid basic dye C.I. Acid Green 16.

2.4. Tri- and Tetrasulfonic Acids

Naphthalene-1,3,5-trisulfonic acid [*6654-64-4*] (**9**), $C_{10}H_8O_9S_3$, M_r 368.34, is extremely soluble in water; the sodium salt crystallizes as the tetrahydrate.

Production. Naphthalene and 65 % oleum are added simultaneously to sulfuric acid monohydrate over a period of 32 h at 30 – 35 °C. The mixture is then heated at 50 °C for 1 h, 70 °C for 1 h, and finally 90 °C for 7 h. This procedure minimizes formation of the 1,3,6-isomer, but a purer product may be obtained by using isolated naphthalene-1,5-disulfonic acid as starting material.

Uses. The total reaction mixture is nitrated and the resulting 8-nitro derivative is reduced to give a mixture of 1-aminonaphthalene-3,6,8- and 4,6,8-trisulfonic acids.

Naphthalene-1,3,6-trisulfonic acid [*86-66-8*] (**10**), $C_{10}H_8O_9S_3$, M_r 368.34, crystallizes as the hexahydrate, *mp* 170 °C.

Production. Naphthalene is initially sulfonated with sulfuric acid monohydrate under programmed temperature control between 80 and 145 °C. Then, 65 % oleum is added gradually at 40 °C and heating is continued for 2.5 h at 145 °C. Trisulfonation is complete after the further addition of 65 % oleum and heating for 3 h at 150 °C. This complex procedure [7] maximizes the formation of **10** with a conversion of up to 75 %.

Uses. The total reaction mixture is nitrated, and the resulting 8-nitro derivative is reduced to give 1-aminonaphthalene-3,6,8-trisulfonic acid (Koch acid), the key intermediate in the production of the important H acid. The crude trisodium salt may be precipitated from the quenched mixture after dilution to 75 % acid strength to give a product (Azoguard) used as a diazo stabilizer.

Naphthalene-1,3,7-trisulfonic acid [*85-49-4*] (**11**), $C_{10}H_8O_9S_3$, M_r 368.34, is much less important than the 1,3,5- and 1,3,6-isomers. It is produced by sulfonation of naphthalene-2,6-disulfonic acid (**7**) with 65 % oleum in sulfuric acid monohydrate [7].

Naphthalene-1,3,5,7-tetrasulfonic acid [*6654-67-7*] (**12**), $C_{10}H_8O_{12}S_4$, M_r 448.4, has no technical importance although it is easily obtained as the end product of the oleum sulfonation of naphthalene, along with the 1,3,7-trisulfonic acid (**11**). In the latter, unlike the 1,3,5- and 1,3,6-trisulfonic acids, direct entry of a fourth sulfonic acid group does not occur.

2.5. Alkylnaphthalenesulfonic Acids

A wide range of mixed alkylnaphthalenesulfonic acids of undefined or undisclosed constitution are produced as surface-active wetting agents and dispersants. For example, methylnaphthalenes are sulfonated with sulfuric acid at 160 °C, or naphthalenesulfonic acids are alkylated with alkenes, higher alcohols, or formaldehyde. Propene or butene produce isopropyl- or butylnaphthalene sulfonates, respectively. Formaldehyde gives the dimer **13** as a simple product from β salt, or polymeric condensation products (**14**), which are important as synthetic tanning agents or as plasticizers for concrete. Dinonylnaphthalene, prepared from naphthalene and nonene, is sulfonated to give derivatives that are important as lubricating oil additives [13].

13

14

3. Naphthols

Naphthols are the most important naphthalene derivatives because they are key intermediates in the production of many chemicals other than dyes and pigments. World production is estimated at 40 000 t/a of 1-naphthol and 100 000 t/a of 2-naphthol.

The production methods for naphthols are as follows (the first four methods are analogous to those for phenols):

1) Alkali fusion of naphthalenesulfonic acids
2) Alkaline hydrolysis of chloronaphthalenes
3) Hydroperoxidation of 2-isopropylnaphthalene to form 2-naphthol and acetone (not applicable to 1-naphthol)
4) Dehydrogenation of tetralones
5) Direct, single-step replacement of the amino group of naphthylamine by a hydroxyl group

The last method is not applicable to phenols, for which the corresponding reaction requires two steps, diazotization of the aminobenzene followed by hydrolysis.

Naphthols resemble phenols in their chemical properties, but their hydroxyl groups are more reactive. For example, they are readily converted to ethers by reaction with alcohols, and to amines by heating with ammonia and bisulfite (Bucherer reaction).

3.1. 1-Naphthol

1-Naphthol [*90-15-3*] (**15**), α-naphthol, 1-naphthalenol, 1-hydroxynaphthalene, $C_{10}H_8O$, M_r 144.16, forms colorless prisms (from toluene) which darken on exposure to air or light. The compound is steam volatile and sublimable. Other physical properties are listed in Table 3.

Table 3. Physical properties of naphthols

Property	1-Naphthol	2-Naphthol
mp, °C	96	123
bp, °C	280	295
d_4	1.224	1.217
Solubility in water, %	0.03 (25 °C)	0.075 (25 °C)
Dissociation constant (H_2O)	1.4×10^{-10} (20 °C)	1.14×10^{-10} (20 °C)

1-Naphthol is reduced by sodium in liquid ammonia to give 5,6,7,8-tetrahydro-1-naphthol and is oxidized by $NaOCl-FeCl_3$ or I_2-KI to give a violet color. It is chlorinated by phosphorus pentachloride at 150 °C to give 1-chloronaphthalene, by sulfuryl chloride to give 4-chloro-1-naphthol,

or by Cl_2-CH_3COOH to give 2,4-dichloro-1-naphthol. Similarly bromine forms 2,4-dibromo-1-naphthol, and this reaction may be used quantitatively for titration.

Nitration of 1-naphthol gives complex mixtures. The crude 2,4-dinitro derivative was used in the mid-1800s as an acid yellow dye comparable to picric acid. Sulfonation at 50 °C readily yields 1-naphthol-2,4-disulfonic acid. Nitrous acid gives mainly the 2-nitroso derivative, contaminated with the 4-nitroso isomer.

Production. Historically 1-naphthol was produced via caustic fusion of naphthalene-1-sulfonic acid, but this was superseded by the I.G. Farbenindustrie process involving hydrolysis of 1-naphthylamine (Section 5.1) with aqueous 22 % sulfuric acid at 200 °C under pressure in a lead-lined autoclave [7]. To obtain a purer product, Union Carbide developed a process based on catalytic oxidation of tetralin to 1-tetralol and 1-tetralone followed by dehydrogenation (see Fig. 2) [27]. The two-stage catalytic process is claimed to give an overall yield of 72 % 1-naphthol, with an overall efficiency of 97 %.

Figure 2. Industrial routes to 1-naphthol and 2-naphthol

Uses. Several important agrochemicals are derived from 1-naphthol. 1-Naphthoxyacetic acid (**17**, R = H) is prepared by aqueous alkylation with chloroacetic acid. Although 2-naphthoxyacetic acid (**31**) appears to be more widely used, ref. [28] suggests that the 1-isomers, especially (**17**, R = Me), have greater herbicidal activity. Devrinol [*15299-99-7*] (**18**), Stauffer's 2-(1-naphthoxy)-*N*,*N*-diethylpropionamide herbicide, is obtained by the reaction of 1-naphthol and *N,N*-diethyl-α-bromopropionamide in MeOH – NaOMe at reflux [29]. Sevin is Union Carbide's insecticide based on 1-naphthyl methylcarbamate [*63-25-2*], carbaryl (**19**), which is produced from 1-naphthyl chloroformate and methylamine [30] or by reaction of 1-naphthol with methyl isocyanate. Its main use lies in the control of earthworms and certain caterpillars. Many analogues and derivatives of **19** have been patented [11].

Important drugs are also derived from 1-naphthol. The ester 1-naphthyl salicylate [*550-97-0*], Alphol (**20**), has been used as an antiseptic and antirheumatic, and ICI's 1-isopropylamino-3-(1-naphthoxy)-2-propanol [*3506-09-0*], Inderal (**21**), is an important member of a new class of adrenergic β-blockers for the treatment of heart disease [31]. Production of **21** involves reaction of **15** with epichlorohydrin followed by isopropylamine.

Related products used as β-blockers or antiarrhythmics include nadoxolol (**22**) and nadolol (**23**). Many analogues and alternative syntheses of this type of compound have been patented [11], [12].

22

23

24

Condensation of 1-naphthol with aniline at 180 °C gives *N*-phenyl-1-naphthylamine (**24**) which is used as a rubber antioxidant.

1-Naphthol is much less important than 2-naphthol as a dye intermediate. Apart from the historical interest in simple azo derivatives such as Orange I (**25**) (GRIESS, 1876; C.I. Acid Orange 20), the equilibrium with the keto form (**26**) is an example of the prevalence of keto forms in many azo naphthol derivatives [32].

Certain diazo components, for example, 1-amino-2-hydroxynaphthalene - 4 - sulfonic acid, under strongly alkaline conditions, couple with 1-naphthol in the 2-position rather than the conventional 4-position. This leads to compounds such as C.I. Mordant Black 3 (**27**) which form stable chromium complexes. Excess diazo compound can lead to disazo acid dyes such as C.I. Acid Brown 43 (**28**).

25

26

27

28

Nitroso compounds can condense with 1-naphthol for example, *N,N*-dimethyl-4-nitrosoaniline reacts to give indophenol (**29**).

29

Halogenated derivatives of 1-naphthol have minor uses as shown by the reaction of 4-chloro-1-naphthol and 4-bromo-1-naphthol with substituted isatin-α-chlorides to form blue indigoid vat dyes [18]

Toxicity. 1-Naphthol is moderately toxic; the dust is liable to cause skin irritation and eye injury [14].

3.2. 2-Naphthol

2-Naphthol [*135-19-3*] (**16**), β-naphthol, 2-naphthalenol, 2-hydroxynaphthalene, $C_{10}H_8O$, M_r 144.16, forms colorless plates upon sublimation, which darken on exposure to air or light. Unlike 1-naphthol it is nonvolatile in steam. Other physical properties are presented in Table 3.

2-Naphthol is reduced with sodium or with hydrogen in the presence of a catalyst to give mainly 1,2,3,4-tetrahydro-2-naphthol (unlike 1-naphthol which gives the arylphenol under the same conditions). Oxidation with ferric chloride forms 2,2′-dihydroxy-1,1′-binaphthyl, with any blue coloration indicating the presence of 1-naphthol. Air oxidation at 300 °C with a vanadium pentoxide catalyst also yields 1,1′-bi-2-naphthol, which dehydrates at higher temperature to the oxide and finally decomposes to give benzoic acid. Treatment with sulfuryl chloride in carbon disulfide or with NaOCl – NaOH leads to 1-chloro-2-naphthol, whereas chlorine in sodium carbonate gives 8-chloro-2-naphthol (plus 1, 1′-bi-2-naphthol). Reaction with phosphorus pentachloride at 150 °C gives

2-chloronaphthalene or at lower temperature, tri-2-naphthyl phosphate (*mp* 111 °C), which can be isolated after treatment of the reaction mixture with alkali. Reaction with one equivalent of bromine in acetic acid gives 1-bromo-2-naphthol, whereas excess bromine yields 1,6-dibromo-2-naphthol. The latter is readily debrominated in dilute mineral acid to yield 6-bromo-2-naphthol. Excess bromine reacts with 2-naphthol at 100 °C to form 1,5,6-tribromo- and 1,3,5,6-tetrabromo-2-naphthol.

Careful nitration with strong nitric acid in acetic acid gives 1,6-dinitro-2-naphthol, whereas nitrous acid readily forms 1-nitroso-2-naphthol [*131-91-9*]. Sulfonation leads to a series of commercially important products (see Chap. 4).

Production. 2-Naphthol is produced by caustic fusion of naphthalene-2-sulfonic acid (Section 2.2). Typically, the sodium salt of the sulfonic acid is added gradually to 50 % sodium hydroxide liquor at 300 °C; the melt is then heated further at 320 °C in a gas-fired iron vessel with vigorous agitation. After completion of the reaction, the melt is run into excess water, possibly including filtrate from the previous batch at a proven tolerable level, and the naphtholate solution is neutralized to pH 8 with dilute sulfuric acid. If the temperature is maintained at >100 °C during neutralization, the crude product comes out of solution as an oil, which is separated, washed with hot water, and distilled under vacuum to give pure 2-naphthol. The molten material is processed through a flaker to give the final product for packaging. The fusion yield is about 80 % of the theoretical value, resulting in an overall yield of 70 % based on naphthalene. Typical specifications for 2-naphthol are (1) clear solution in dilute caustic soda, (2) *mp* 120.5 °C, and (3) 1-naphthol content <0.3 %.

The newer method of manufacture (see Fig. 2) is economically and environmentally favored in the United States, because despite requiring three stages, it is more amenable to continuous operation with recycle streams. The alkylation and isomerization are carried out up to 240 °C with a phosphoric acid catalyst [33]. Final catalytic oxidation at 90 – 110 °C gives the hydroperoxide, which is cleaved with dilute sulfuric acid to give 2-naphthol in high overall yield in spite of modest oxidation conversion.

Uses. The sulfonated and carboxylated derivatives are described in Chapter 4 and Section 3.4.

The simple ether derivatives, 2-methoxynaphthalene [*93-04-9*], nerolin, and 2-ethoxynaphthalene [*93-18-5*], nerolin "new", are readily prepared by conventional alcohol esterification processes for use in perfume formulation and, more recently as intermediates for drugs. The β-hydroxyethyl ether, anavenol (**30**), prepared by condensation of 2-naphthol with ethylene chlorohydrin or ethylene oxide, has been used as an animal sedative. Reaction of 2-naphthol with chloroacetic acid in aqueous alkaline medium gives 2-naphthoxyacetic acid (**31**), which is used as a growth promoter for fruit.

30

31

The lactate, benzoate, and salicylate esters have been used as antiseptics and are improvements of the naphthols themselves.

Reaction of 2-naphthol with aniline at 180 °C gives *N*-phenyl-2-naphthylamine (PBN, **32**) an antioxidant for rubber processing which is gradually being displaced by improved products.

32

33

The major pharmaceutical products based on 2-naphthol are the antifungal tolnaftate (**33**), produced by reaction with thiophosgene and *N*-methyl-*m*-toluidine [34]; the semisynthetic penicillin nafcillin (**34**), produced via 2-ethoxynaphthalene; and the antirheumatic naproxen (**35**), produced via 2-methoxynaphthalene.

34

35

The C-alkylation of 2-naphthol by using 2-chlorocyclohexanone in boiling dioxane in the presence of potassium carbonate has been ex-

ploited in the preparation of the antitussive naphthanone (**36**).

36

2-Naphthol is used in solvent dyes, e.g., C.I. Solvent Yellow 14 (**37**, R = H); in acid dyes, e.g., C.I. Acid Orange 7 (**37**, R = SO_3H); in metallizable dyes, e.g., C.I. Mordant Black 15 (**38**); and in pigments, e.g., C.I. Pigment Red 3 (**39**).

37

38

39

However, 3-hydroxy-2-naphthoic acid and derived arylamides (Section 3.4) are more important coupling components for pigments than is 2-naphthol.

Toxicity. 2-Naphthol is moderately toxic but less of a skin irritant than 1-naphthol [15].

3.3. Naphthalenediols

All ten isomeric naphthalenediols are known. They are usually prepared by alkali fusion of sulfonic acids or by acid hydrolysis of aminonaphthalenes, provided appropriately substituted compounds are available as precursors. With α,β-disubstituted naphthalenes, hydroxylation takes place more readily in the α-position; this is particularly important if hydroxynaphthalenesulfonic acids (Chap. 4) are required [12].

Conversely, with amination of dihydroxynaphthalenes by the Bucherer reaction, the β-position is more readily attacked. Thus, 1,7-dihydroxynaphthalene gives 7-amino-1-naphthol.

Of the ten dihydroxynaphthalenes, only 1,5-naphthalenediol has significant applications.

1,5-Naphthalenediol [*83-56-7*], 1,5-dihydroxynaphthalene, Azurol, $C_{10}H_8O_2$, M_r 160.16, forms colorless needles (from aqueous methyl cellosolve). The compound is sublimable, readily soluble in ether and acetone, but only sparingly soluble in water and hydrocarbons. It is oxidized to 5-hydroxy-1,4-naphthoquinone (juglone) by CrO_3. Amination gives 1,5-naphthalenediamine; coupling with diazotized anilines occurs in the 2- or 4-position.

Production [7]. The sodium salt of naphthalene-1,5-disulfonic acid (Section 2.3) is added gradually to excess 75 % sodium hydroxide. The mixture is heated under pressure to 276 °C over the course of 7 h and the reaction is completed by heating for a further 5 h at this temperature. After precipitation with sulfuric acid, the product is isolated in 90 % yield.

Uses. 1,5-Naphthalenediol is used as a coupling component in azo dyes as exemplified in the metallizable (Cr) wool dye, C.I. Mordant Black 9 (**40**).

40

1,2-Naphthalenediol [*574-00-5*], *mp* 108 °C, is prepared by reduction of 1,2-naphthoquinone with hydrazine hydrate or sodium dithionite. It is oxidized under mild conditions to 1,2-naphthoquinone and couples with diazotized anilines in the 4-position.

1,3-Naphthalenediol [*132-86-5*], naphthoresorcinol, *mp* 124 °C, is synthesized by hydrolysis of 1,3-naphthalenediamine with sulfuric acid; by heating 1-amino-3-hydroxy-naphthalene-4-sulfonic acid with acid; or by cyclization of ethyl phenylacetoacetate. It is used as an analytical reagent for sugars and glucuronic acid in urine. It is oxidized in alkaline solution to 2-hydroxy-1,4-naphthoquinone and reacts with ammonia at 140 °C to give 3-amino-1-naphthol and 1,3-naphthalenediamine.

1,4-Naphthalenediol [*571-60-8*], *mp* 195 °C, is synthesized by reduction of 1,4-naphthoquinone with sodium dithionite, or by hydrolysis of 4-amino-1-naphthol with 20 % sulfuric acid. It undergoes oxidation to give 1,4-naphthoquinone; amination to give 4-amino-1-naphthol; and methylation (MeOH – HCl) to give 4-methoxy-1-naphthol.

1,6-Naphthalenediol [*575-44-0*], *mp* 138 °C, is synthesized by caustic fusion of naphthalene-1,6-disulfonic acid at 330 °C. It couples with diazotized anilines to form disazo and trisazo derivatives.

1,7-Naphthalenediol [*575-38-2*], *mp* 181 °C, is prepared by caustic fusion of 2-hydroxynaphthalene-8-sulfonic acid at 300 °C or by acid desulfonation of 2,8-dihydroxynaphthalene-6-sulfonic acid. It couples with diazotized anilines to form monoazo and disazo derivatives.

1,8-Naphthalenediol [*569-42-6*], *mp* 144 °C, is produced by caustic fusion of naphthosultone (Section 4.2) or naphthosultam (Section 6.1), and by acid desulfonation of 1,8-dihydroxynaphthalene-4-sulfonic acid. It is oxidized to juglone by chromium(VI) oxide; gives a dark green color with iron(III) chloride; undergoes amination at 300 °C to give 1,8-naphthalenediamine; and couples with diazotized anilines in the 4-position.

2,3-Naphthalenediol [*92-44-4*], *mp* 161 °C, is prepared by caustic fusion of 3-hydroxynaphthalene-2,6-disulfonic acid followed by treatment with dilute sulfuric acid under pressure, or by acid desulfonation of 2,3-dihydroxynaphthalene-6-sulfonic acid. It gives a dark blue color with iron(III) chloride; is aminated to 2-amino-3-naphthol at 140 °C and 2,3-naphthalenediamine at 240 °C; and couples with diazotized anilines in the 1- or 1,4-positions.

2,6-Naphthalenediol [*581-43-1*], 2,6-naphthohydroquinone, *mp* 222 °C, is synthesized by potassium hydroxide fusion of 2-hydroxynaphthalene-6-sulfonic acid at 295 °C. It undergoes amination at 250 °C to give 2,6-naphthalenediamine and couples with diazotized anilines in the 1-position under acid conditions or the 1,5-positions under alkaline conditions.

2,7-Naphthalenediol [*582-17-2*], *mp* 194 °C, is produced by caustic fusion of naphthalene-2,7-disulfonic acid or 2-hydroxynaphthalene-7-sulfonic acid at 300 °C. It undergoes amination at 250 °C to give 2,7-naphthalenediamine and couples with diazotized anilines in the 1-position or in the 1,8-positions. It forms a resin with formaldehyde.

3.4. Hydroxynaphthoic Acids

The industrially important hydroxynaphthoic acids are all produced by carboxylation (with CO_2) of the corresponding sodium or potassium naphtholate (Kolbe – Schmitt reaction). 3-Hydroxy-2-naphthoic acid (BON acid) is one of the most important naphthalene-based colorant intermediates. Arylamide derivatives were introduced in 1912 as improved azoic dyes, replacing 2-naphthol which had been in use since 1880 as a component in ice colors. Apart from their use in azoic dyes for cotton, these arylamides are intermediates for important pigments.

For isomers that are not accessible by carboxylation, the precursor cyano group is introduced by Sandmeyer reaction of the appropriate aminonaphthalenesulfonic acid, followed by hydrolysis and caustic fusion.

Although carboxylation of naphtholates may be carried out in a solvent whereby the polarity of the solvent has a marked effect on the reaction [35], large-scale operation is usually effected by using a dry melt in a rotating baker or specially designed agitated vessel. Whereas sodium α-naphtholate yields 1-hydroxy-2-naphthoic acid at 130 °C and sodium β-naphtholate yields 2-hydroxy-1-naphthoic acid at 120 °C; somewhat surprisingly, 3-hydroxy-2-naphthoic acid is produced from β-naphthol above 200 °C. The mechanism is not clear, and the course of the reaction is affected by temperature, pressure, alkali metal, and the presence of water [36]. However, the identified intermediate stages from sodium β-naphtholate are the formation of **41** at 120 °C and its conversion to equimolar quantities of **42** and 2-naphthol at 145 °C, which explains why the maximum yield is only 50 %. At 200 °C, **42** rearranges to **43**, which also has a maximum yield of 50 %.

41 42 43

The Marasse modification (1893) of the Kolbe – Schmitt reaction uses potassium carbonate with carbon dioxide and in certain cases gives better yields [36]. This has been confirmed for hydroxynaphthoic acids at 300 °C [37]. However, with potassium β-naphtholate an alternative rearrangement can take place, in which 6-hydroxy-2-naphthoic acid is coproduced at 220 °C.

2-Hydroxy-1-naphthoic acid [*2283-08-1*], $C_{11}H_8O_3$, M_r 188.17, has a *mp* of 156 – 157 °C (decomp. to 2-naphthol and CO_2). The monosodium salt is unstable in hot aqueous solution. 2-Hydroxy-1-naphthoic acid is decarboxylated by nitrous acid, forming 1-nitroso-2-naphthol, and by diazo salts, forming a 1-azo-2-naphthol. An ethanolic solution of 2-hydroxy-1-naphthoic acid gives a dark blue color with iron(III) chloride. Chlorosulfonic acid at 30 °C gives the 6-sulfonyl chloride derivative.

Production. [7] Treatment of the dried sodium or potassium salt of 2-naphthol with carbon dioxide at 120 °C under pressure gives an 80 % yield of product after careful work-up. Solvents such as toluene, tetralin, or diphenyl oxide are patented alternatives [15].

Uses. 2-Hydroxy-1-naphthoic acid is an intermediate of minor importance in the synthesis of azo dyes.

3-Hydroxy-1-naphthoic acid [*19700-42-6*], *mp* 248 – 249 °C, is prepared by hydrolysis of diazotized 3-amino-1-naphthoic acid with boiling aqueous copper sulfate. It gives a reddish brown color with iron(III) chloride. Coupling with diazo compounds occurs in the 4-position.

4-Hydroxy-1-naphthoic acid [*7474-97-7*], *mp* 188 – 189 °C, is synthesized by potassium hydroxide fusion (200 °C) of 4-sulfo-1-naphthoic acid or 4-cyanonaphthalene-1-sulfonic acid (from 1-aminonaphthalene-4-sulfonic acid). It undergoes decarboxylation with bromine, nitrous acid, or diazo salts to form the corresponding 4-derivative.

5-Hydroxy-1-naphthoic acid [*2437-16-3*], *mp* 236 °C, is prepared by potassium hydroxide fusion (245 °C) of 1-cyanonaphthalene-5-sulfonic acid. It couples with diazo compounds in the 8-position.

6-Hydroxy-1-naphthoic acid [*2437-17-4*], *mp* 213 °C, is produced by hydrolysis (10 % KOH) and potassium hydroxide fusion (260 °C) of 1-cyanonaphthalene-6-sulfonic acid (from 1-aminonaphthalene-6-sulfonic acid and cyano-Sandmeyer reaction).

7-Hydroxy-1-naphthoic acid [*2623-37-2*], *mp* 256 °C, is synthesized by hydrolysis (50 % KOH) of 8-cyano-2-naphthol (from 8-amino-2-naphthol and cyano-Sandmeyer reaction). It couples in the 8-position with diazo compounds.

8-Hydroxy-1-naphthoic acid [*1769-88-6*], *mp* 169 °C, is prepared by hydrolysis (60 % H_2SO_4) of 8-cyanonaphthalene-1-sulfonic acid and caustic fusion of the resulting anhydride of 8-sulfo-1-naphthoic acid. It couples with diazo compounds in the 5-position.

1-Hydroxy-2-naphthoic acid [*86-48-6*], $C_{11}H_8O_3$, M_r 188.17, *mp* 200 °C, is only sparingly soluble in hot water but readily soluble in alkali and ethanol. It couples with diazo compounds in the 4-position and, with excess, in the 4,7-positions. It is sulfonated by oleum to give the 4-sulfonic and then the 4,7-disulfonic acids. Halogenation occurs in the 4-position, and nitrosation gives 2-nitroso-1-naphthol.

Production. [7] Treatment of the dried sodium salt of 1-naphthol with carbon dioxide at 135 °C under pressure gives an 80 % yield of product.

Uses. 1-Hydroxy-2-naphthoic acid is used as an intermediate for azo and triphenylmethane dyes and, more recently, for color-film dyes [38].

3-Hydroxy-2-naphthoic acid [*92-70-6*], BON acid, $C_{11}H_8O_3$, M_r 188.17, *mp* 222 °C, forms pale yellow crystals from aqueous ethanol. Alkaline solutions have a green fluorescence. Aqueous ferric chloride produces a blue color, and warming with $CHCl_3$– NaOH results

in a green color. Oxidation with alkaline permanganate gives 2-carboxyphenylglyoxylic acid and then phthalic acid. Dry distillation produces dibenzoxanthone. Bromination gives the 4,7-dibromo derivative; nitration, the 4-nitro derivative; and sulfonation with oleum, the 5,7-disulfonic acid derivative.

Production is invariably by the Kolbe – Schmitt reaction of carbon dioxide with the dried sodium salt of 2-naphthol at 220 – 260 °C [7]. Many improvements in both process and equipment have been developed. The main problems are removal of the 50 % unreacted 2-naphthol and avoidance of a tarry byproduct. Yields of 80 % based on the amount of 2-naphthol consumed are possible despite the low conversion.

Uses. The major use of 3-hydroxy-2-naphthoic acid as a dye intermediate is reflected by the quoted production figure of 21 000 t/a in Japan alone. With annual imports of 2500 t/a in the United States, BON acid is the largest imported naphthalene intermediate and one of the largest of all dye and pigment intermediates. Naphtol AS (Naphtol Anilid-Säure) (**44**) represents the most important arylamide derivative. It is produced by forming the acid chloride of 3-hydroxy-2-naphthoic acid with phosphorus trichloride in a solvent such as toluene and then adding aniline for condensation in situ. Many other arylamides are manufactured similarly by using a range of substituted anilines and other arylamines. These arylamides are used in azoic dyes or as intermediates for azo pigments.

Sulfonation of 3-hydroxy-2-naphthoic acid with 98 % sulfuric acid at 30 °C gives a mixture of the 5- and 7-sulfonic acid derivatives, which can be separated via their potassium salts. After isolation, the more soluble 5-isomer can be fused with NaOH – KOH at 260 °C to give 3,5-dihydroxy-2-naphthoic acid (**45**).

44

45

4-Hydroxy-2-naphthoic acid [*1573-91-7*], *mp* 225 – 226 °C, is produced by air oxidation of 1-tetralone-3-carboxylic acid.

5-Hydroxy-2-naphthoic acid [*2437-18-5*], *mp* 215 – 216 °C, is prepared by potassium hydroxide fusion (260 °C) of 5-sulfo-2-naphthoic acid.

6-Hydroxy-2-naphthoic acid [*16712-64-4*], *mp* 245 – 248 °C, is synthesized by carboxylation of the potassium salt of 2-naphthol at 170 – 230 °C. It couples with diazo compounds in the 5-position and undergoes sulfonation in the 4- and 7-positions.

7-Hydroxy-2-naphthoic acid [*613-17-2*], *mp* 274 °C, is prepared by sulfonation (160 °C) of 2-naphthoic acid to give the 7-sulfo derivative, followed by potassium hydroxide fusion at 260 °C. It couples with diazo compounds in the 8-position.

8-Hydroxy-2-naphthoic acid [*5776-28-3*], *mp* 229 °C, is produced by the cyano-Sandmeyer reaction of 2-aminonaphthalene-8-sulfonic acid, followed by hydrolysis and potassium hydroxide fusion.

Di- and trihydroxynaphthoic acids and hydroxy- and dihydroxynaphthalenedicarboxylic acids are also obtainable, but are of only academic interest at present [5].

4. Hydroxynaphthalenesulfonic Acids

The importance of the various mono- and dihydroxynaphthalene mono- and disulfonic acids is demonstrated by the fact that about 25 products in this group have been produced over the years with many of them still available and referred to by code names (see Table 1). Most of the products have been used as azo dye coupling components, but they are equally important as intermediates for aminonaphthalenesulfonic acids (Chap. 6) and aminohydroxynaphthalenesulfonic acids (Chap. 8). Only those isomers that have a history of commercial use are dealt with on an individual basis. Many of the other isomers are also obtainable [5] and may be of present or future interest.

Because in usage this group of products is considered to be derived from 1-naphthol or 2-naphthol they are dealt with on this basis rather

than as hydroxy derivatives of naphthalenesulfonic acids. The latter alternative is the IUPAC convention, and these more formal names are given in parentheses alongside alternative trivial names.

4.1. Production and Properties

Production depends on four main routes to achieve the required substitution patterns. All routes involve selectivity and separation at some stage, usually the sulfonation stage (cf. Section 2.1). The use of HPLC is essential for following separations and assessing the purity of products.

Direct Sulfonation of Naphthols. The reaction of 1-naphthol with sulfuric acid at 60 °C gives mainly 1-hydroxynaphthalene-2-sulfonic acid (**46**) with a small proportion of 1-hydroxynaphthalene-4-sulfonic acid (**47**), from which it can be separated. Increasing the sulfuric acid – naphthol ratio and raising the temperature produces first 1-hydroxynaphthalene-2,4-disulfonic acid (**48**) and then 1-hydroxynaphthalene-2,4,7-trisulfonic acid (**49**).

Sulfonation of 2-naphthol is more complex because concentration and amount of sulfonating agent, temperature, and reaction time all significantly influence the nature and yield of product. At 0 – 20 °C, sulfuric acid rapidly forms 2-hydroxynaphthalene-1-sulfonic acid (**50**); with longer reaction times a second sulfonic acid group is introduced to form 2-hydroxynaphthalene-1,6-disulfonic acid (**51**). At 50 – 55 °C, sulfonation occurs in the 6- and 8-positions giving **52** and **53**. More vigorous conditions lead to the disulfonic acids **54** and **55** with some 1- and, to a lesser extent, 8-desulfonation being involved to affect isomer yields. Finally, oleum at higher temperature sulfonates the disulfonic acids to give 2-hydroxynaphthalene-3,6,8-trisulfonic acid (**56**).

Alkali Fusion of Naphthalenedisulfonic Acids or Hydroxynaphthalenedi- and Trisulfonic Acids (cf. Chap. 3). Hydrolysis of sulfonic acid substituents to form substituted naphthols is a key process with selective monoreaction able to be controlled in disulfonic acids. This is easier with α,β-disulfonic acids, in which reaction at the α-group is much more facile.

The following ten derivatives (**57** – **66**) prepared by this route are all commercially important. The asterisks indicate hydroxyl groups introduced by the fusion process.

57

58

59

60

61

62

63

64

65

66

Hydrolysis of Aminonaphthalenesulfonic Acids. Certain naphthylaminesulfonic acids resemble 1-naphthylamine in hydrolyzing to the corresponding naphthol on prolonged heating with dilute sulfuric acid at 180 – 200 °C under pressure. This process is preferred for the synthesis of 1-hydroxynaphthalene-3-sulfonic acid (**67**), 2-hydroxynaphthalene-5,7-disulfonic acid (**68**), and 1-hydroxynaphthalene-3,6,8-trisulfonic acid (**69**).

67

68

69

An alternative to sulfuric acid hydrolysis is the use of sodium bisulfite in a so-called reverse-Bucherer reaction. This is the preferred process for 1-hydroxynaphthalene-4-sulfonic acid (**47**).

47

Finally, where neither sulfuric acid nor bisulfite hydrolysis is applicable, indirect hydrolysis via diazotization of the aminonaphthalenesulfonic acid and treatment with dilute sulfuric acid are employed. Although this method is generally applicable, it is more expensive to operate on a large scale, and its use is confined to derivatives of 1-hydroxynaphthalene-8-sulfonic acid.

Acid Desulfonation of Hydroxynaphthalenedi- or Trisulfonic Acids. With certain substitution patterns, sulfonic acid groups may be removed by heating with 40 % sulfuric acid. This reaction should be regarded as reverse sulfonation rather than hydrolysis, and includes the examples already given in Section 3.3 for the formation of naphthalenediols. An example is the selective desulfonation of 2-hydroxynaphthalene-4,8-disulfonic acid to give 2-hydroxynaphthalene-4-sulfonic acid (**70**).

70

Although hydroxynaphthalenesulfonic acids are usually soluble in water and more soluble than their alkali-metal salts, they can be isolated by salting out from solution. The hydroxyl group is dissociated in aqueous solution as shown by the dissociation constants (Table 4) [15].

Table 4. Dissociation constants for hydroxyl groups of hydroxynaphthalenesulfonic acids in water at 20 °C

Hydroxynaphthalenesulfonic acid	pK_2	pK_3	pK_4
1-Hydroxynaphthalene-3-sulfonic acid	8.7		
1-Hydroxynaphthalene-4-sulfonic acid	8.2		
1-Hydroxynaphthalene-5-sulfonic acid	9.0		
2-Hydroxynaphthalene-1-sulfonic acid	10.96		
2-Hydroxynaphthalene-6-sulfonic acid	9.1		
2-Hydroxynaphthalene-7-sulfonic acid	9.2		
1,8-Hydroxynaphthalene-4-sulfonic acid	5.33	>12.7	
2,3-Hydroxynaphthalene-6-sulfonic acid	8.24	12.13	
2,8-Hydroxynaphthalene-6-sulfonic acid	8.61	10.21	
1,8-Hydroxynaphthalene-3,6-sulfonic acid		5.53	>12.75

Purification and characterization are difficult unless chromatographic standards have been obtained [20]. The simplest form of analysis is to determine strength by coupling via titration of an alkaline solution with a standard solution of a diazonium salt.

Many of the hydroxynaphthalenesulfonic acids are used as azo coupling components. Where they serve as precursors in the synthesis of downstream intermediates the most common reactions are amination of the hydroxyl group by the Bucherer reaction to form aminonaphthalenesulfonic acids (Chap. 6) and caustic fusion of the sulfonic acid group to form naphthalenediols (Section 3.3) or their sulfonic acid derivatives.

4.2. 1-Hydroxynaphthalenesulfonic Acids

1-Hydroxynaphthalene-2-sulfonic acid [*567-18-0*] (**46**), Baum's acid, $C_{10}H_8O_4S$, M_r 224.23, is sparingly soluble in water and is precipitated from aqueous solution by hydrochloric acid. Coupling with diazo compounds and nitrosation both take place in the 4-position. Sulfonation gives 1-naphthol-2,4-disulfonic acid and nitration gives 2,4-dinitro-1-naphthol.

Production. The reaction of 1-naphthol with oleum in the cold yields a mixture of the 2- and 4-sulfonic acids; the former may be separated from the aqueous quenched reaction mixture by salting out the potassium salt after removing unreacted 1-naphthol.

1-Hydroxynaphthalene-3-sulfonic acid [*3771-14-0*] (**67**) (4-hydroxynaphthalene-2-sulfonic acid), $C_{10}H_8O_4S$, M_r 224.2, and its salts are very soluble in water. Coupling with diazo compounds occurs in the 2-position with weak diazo compounds, but in the 4-position with strong diazo compounds such as diazotized nitroanilines. Heating with ammonia at 170 °C gives 1,3-naphthalenediamine.

Production. 1-Aminonaphthalene-3-sulfonic acid (Section 6.1) is heated with dilute sulfuric acid by using high-pressure steam to maintain a pressure of 1 MPa for 20 h [7]. After cooling, screening, and adding salt to the hot liquor, the sodium salt crystallizes on cooling and is isolated in 80 % yield.

Uses. 1-Hydroxynaphthalene-3-sulfonic acid is used as a coupling component for the production of direct dyes.

1-Hydroxynaphthalene-4-sulfonic acid [*84-87-7*] (**47**) (4-hydroxynaphthalene-1-sulfonic acid), Nevile and Winther's acid, NW acid, $C_{10}H_8O_4S$, M_r 224.23, and its salts are water soluble, but the sodium salt may be precipitated from solution by salting out. Coupling with diazo compounds takes place in the 2-position. Nitration yields 2,4-dinitro-1-naphthol, whereas nitrosation gives 2-nitroso-1-hydroxynaphthalene-4-sulfonic acid. Sulfonation leads to a mixture of 1-hydroxynaphthalene-2,4-di- and 2,4,7-trisulfonic acids.

Production. Sodium naphthionate (Section 6.1) in aqueous alkaline solution is heated with sodium bisulfite and liquid sulfur dioxide for 24 h at 95 °C [7]. The batch is heated with excess lime to hydrolyze the bisulfite compound and boil off ammonia. After filtration the solution of the calcium salt of the product is neutralized with sodium carbonate, and precipitated calcium carbonate is filtered off. The solution of the sodium salt can be used directly as a coupling component, or salt can be added to precipitate and isolate the product.

An alternative synthesis involves selective sulfonation of 1-naphthol in the 4-position by using liquid sulfur trioxide in solvents such as trichloroethane or tetrachloroethane.

Uses. 1-Hydroxynaphthalene-4-sulfonic acid is used as a coupling component for a wide range of acid azo dyes, e.g., C.I. Acid Orange 19, C.I. Mordant Brown 35, and C.I. Food Red 3 (**71**).

71

1-Hydroxynaphthalene-5-sulfonic acid [*117-59-9*] (**57**) (5-hydroxynaphthalene-1-sulfonic acid), oxy L acid, Azurin acid, $C_{10}H_8O_4S$, M_r 224.2, and its salts are very soluble in water, but the sodium salt may be precipitated from solution by salting out. Coupling with diazo compounds normally occurs in the 2-position but takes place in the 4-position with stronger diazo compounds such as diazotized nitroanilines. Sulfonation yields 1-hydroxynaphthalene-2,5-disulfonic acid; vigorous alkali fusion gives 1,5-dihydroxynaphthalene. Bromination in acetic acid yields 2,3-dibromo-1,4-naphthoquinone-5-sulfonic acid.

Production. The disodium salt of naphthalene-1,5-disulfonic acid (Section 2.3) is heated in an autoclave with 20 % sodium hydroxide at 230 °C for 24 h to selectively hydrolyze one sulfonic acid group [7]. Dilution, salting out, and acidification give a technical product in 90 % yield. A purer product, in lower yield, is obtained by acidification of the diluted melt with sulfuric acid, followed by liming and salting out.

Uses. 1-Hydroxynaphthalene-5-sulfonic acid is used as a coupling component for a range of azo colorants, for example, C.I. Pigment Red 54 and C.I. Mordant Black 29.

1-Hydroxynaphthalene-7-sulfonic acid [*20191-62-2*] (**72**) (8-hydroxynaphthalene-2-sulfonic acid), $C_{10}H_8O_4S$, M_r 224.2, is very soluble in water, and most of its metal salts are also readily soluble. It couples with diazotized 4-nitroaniline to give the 2,4-disazo compound. Nitration gives 2,4-dinitro-1-naphthol-7-sulfonic acid, which was known as Flavianic acid when used as a yellow dye for wool.

Production. 1-Naphthol is sulfonated with concentrated sulfuric acid at 130 °C to give a mixture of 2,7- and 4,7-disulfonic acids. This mixture is difficult to separate, but dilution with water and heating the resulting dilute sulfuric acid solution at 120 °C for 30 min result in selective desulfonation in the 2- and 4-positions [39].

72

1-Hydroxynaphthalene-8-sulfonic acid [*117-22-6*] (**74**) (8-hydroxynaphthalene-1-sulfonic acid), $C_{10}H_8O_4S$, M_r 224.2, crystallizes as the monohydrate with *mp* 106 °C. Sulfonation gives 1-hydroxynaphthalene-4,8-disulfonic acid, and alkali fusion with potassium hydroxide at 230 °C yields 1,8-dihydroxynaphthalene. Coupling with diazo compounds occurs in the 2-position.

Production. 1-Aminonaphthalene-8-sulfonic acid (Section 6.1) is diazotized over 16 h at 50 °C and then heated to 80 °C [7]. After cooling, the precipitated naphthosultone (**73**) is filtered off and washed. The sultone is heated with dilute sodium hydroxide at 100 °C, which causes ring opening; the product is isolated after salting out.

73 **74**

Uses. The naphthosultone (**73**) is usually satisfactory as an intermediate for further processing; however, for azo dye preparation the free naphthol (**74**) must be used, for example, in C.I. Acid Black 54 and C.I. Acid Blue 158 (the chromium complex of **75**).

75

4.3. 2-Hydroxynaphthalenesulfonic Acids

2-Hydroxynaphthalene-1-sulfonic acid [*567-47-5*] (**50**), oxy Tobias acid, $C_{10}H_8O_4S$, M_r 224.2, and its salts are very soluble in water; neutral solutions give a strong blue color with iron(III) chloride. The sulfonic acid group is sufficiently labile for desulfonation to take place slowly in aqueous solution and rapidly with diazo compounds to form 1-azo-2-hydroxynaphthalene derivatives (i.e., the same product as from 2-naphthol), and with bromine to form 1-bromo-2-hydroxynaphthalene. Low-temperature sulfonation gives 2-hydroxynaphthalene-1,6-disulfonic acid, whereas higher temperatures result in 1-desulfonation and formation of 2-hydroxynaphthalene-6- and 8-sulfonic acids. Nitration affords 1,6-dinitro-2-hydroxynaphthalene.

Production. 2-Naphthol is dissolved in 1,2-dichloroethane and chlorosulfonic acid is added at 0 °C; the reaction is allowed to go to completion at low temperature. During work-up and isolation, desulfonation is avoided by careful extraction of the product into aqueous alkali and salting out of the sodium salt. Alternative solvents, such as dichloromethane, tetrachloroethane, or 1,2-dichlorobenzene, and other sulfonating agents, (e.g., liquid sulfur trioxide) can be used.

Uses. Virtually all the 2-hydroxynaphthalene-1-sulfonic acid produced is converted to 2-aminonaphthalene-1-sulfonic acid (Tobias acid) by amination (Section 6.1).

The calcium salt Asaprol is soluble in aqueous ethanol and has been used in place of gypsum in surgical plaster.

2-Hydroxynaphthalene-4-sulfonic acid [*6357-85-3*] (**70**) (3-hydroxynaphthalene-1-sulfonic acid), $C_{10}H_8O_4S$, M_r 224.2, and its salts are extremely soluble in water and difficult to isolate. It undergoes nitrosation and couples with diazo compounds in the 1-position. Sulfonation with oleum gives 2-hydroxynaphthalene-4,8-disulfonic acid. Amination with ammonia under pressure gives 2-aminonaphthalene-4-sulfonic acid.

Production. 2-Hydroxynaphthalene-4,8-disulfonic acid (Section 4.5) is heated with dilute sulfuric acid at 190 °C for 10 h in an autoclave under pressure [7]. After cooling, a small quantity of 2-naphthol is filtered off and sulfuric acid is removed by liming. The resulting solution of the calcium salt of the product is converted to the sodium salt, which is used directly as a solution or evaporated to isolate the product.

2-Hydroxynaphthalene-6-sulfonic acid [*93-01-6*] (**52**) (6-hydroxynaphthalene-2-sulfonic acid), Schaeffer acid, $C_{10}H_8O_4S$, M_r 224.23, is readily soluble in water, from which it can be recrystallized as the monohydrate (*mp* 129 °C). The sodium salt is sparingly soluble in cold water (1.7 %) but forms a 30 % solution at 80 °C. Coupling with diazo compounds results in substitution in the 1-position as does treatment with bromine, nitrous acid, or oleum. Fusion with potassium hydroxide gives 2,6-dihydroxynaphthalene (Section 3.3), amination gives 2-aminonaphthalene-6-sulfonic acid (Section 6.1), and sulfonation (20 % oleum, 25 °C) results in 2-hydroxynaphthalene-1,6-disulfonic acid.

Production. 2-Naphthol is added to a mixture of sulfuric acid and sodium sulfate, and the reaction is continued at 90 °C for 12 h [7]. After pouring the reaction mixture into water, the sodium salt of the product is precipitated by addition of salt and filtered at 60 °C to separate the isomers.

Uses. 2-Hydroxynaphthalene-6-sulfonic acid is used as a coupling component for a wide range of azo dyes, e.g., C.I. Acid Orange 12, C.I. Food Yellow 3, and C.I. Food Orange 2 (**76**). It is also used as an intermediate for more highly substituted dye components and synthetic tanning agents. The 1-nitroso derivative forms an iron complex (C.I. Acid Green 1) which was formerly used as a wool dye.

76

2-Hydroxynaphthalene-7-sulfonic acid [*92-40-0*] (**58**) (7-hydroxynaphthalene-2-sulfonic acid), F acid, Cassella acid, $C_{10}H_8O_4S$, M_r 224.23, is soluble in water, from which it

can be recrystallized as the monohydrate (*mp* 89 °C). The sodium and potassium salts are also readily soluble, but the barium salt is sparingly soluble. Iron(III) chloride gives a dark blue color with neutral solutions of **58**. Azo coupling and nitrosation occurs in the 1-position. Sulfonation gives a variety of products depending on the conditions.

Production. Naphthalene-2,7-disulfonic acid (Section 2.3) is heated with aqueous sodium hydroxide under pressure at 230 °C for 5 h and then at 260 °C for another 5 h. After neutralizing and screening, the liquor is acidified to precipitate the product, which is isolated after boiling off the sulfur dioxide and cooling to 30 °C.

Uses. 2-Hydroxynaphthalene-7-sulfonic acid is used as an intermediate in the production of 2-aminonaphthalene-7-sulfonic acid (Section 6.1), 2-hydroxynaphthalene-3,7-disulfonic acid, and 2,7-dihydroxynaphthalene (Section 3.3). It has minor uses as an azo coupling component.

2-Hydroxynaphthalene-8-sulfonic acid [*132-57-0*] (**53**) (7-hydroxynaphthalene-1-sulfonic acid), crocein acid, Bayer's acid, $C_{10}H_8O_4S$, M_r 224.23, is more soluble in water than 2-hydroxynaphthalene-6-sulfonic acid and cannot readily be isolated. Its salts are also more soluble than their 2,6-analogues and are difficult to isolate. On evaporation of its solutions, the free acid (**53**) decomposes to 2-naphthol. Coupling with diazo compounds takes place in the 1-position, but reaction is hindered by the peri-sulfonic acid group so that concentrated conditions and sometimes catalysts are required. Above 60 °C, sulfuric acid converts **53** into 2-hydroxynaphthalene-6-sulfonic acid; sulfonation then proceeds further to give the 6,8-disulfonic acid. Amination (Bucherer reaction) gives 2-aminonaphthalene-8-sulfonic acid (Section 6.1).

Production. 2-Naphthol reacts with excess 98 % sulfuric acid at 20 – 35 °C to form 2-hydroxynaphthalene-1-sulfonic acid. Further reaction at 55 – 60 °C produces a mixture of 6- and 8-sulfonic acids, from which the less soluble 6-isomer is separated before and after liming to give a crude crocein acid liquor containing 16 % Schaeffer acid. If pure **53** is required, the latter is separated by selective coupling with diazotized *o*-toluidine and removal of the precipitated azo dye.

Uses. Crocein acid is used as a coupling component for azo dyes e.g., C.I. Acid Red 25 (**77**).

77

4.4. 1-Hydroxynaphthalenedisulfonic Acids

1-Hydroxynaphthalene-3,6-disulfonic acid [*578-85-8*] (**59**) (4-hydroxynaphthalene-2,7-disulfonic acid), RG acid, Violet acid, $C_{10}H_8O_7S_2$, M_r 304.3: the free acid (pK_a 8.56) and its alkalimetal salts are readily soluble in water, but the acid sodium salt can be precipitated from concentrated solution with salt. Sulfonation with oleum at 125 °C gives a tetrasulfonic acid, and amination with ammonia and ammonium chloride at 160 °C gives a mixture of 3-amino-1-hydroxynaphthalene-6-sulfonic acid and 6-amino-1-hydroxynaphthalene-3-sulfonic acid. Alkali fusion at 170 °C gives mainly 1,6-dihydroxynaphthalene-3-sulfonic acid, and at 250 °C yields 1,3,6-trihydroxynaphthalene. Diazo coupling takes place in the 2-position.

Production. Naphthalene-1,3,6-trisulfonic acid (Section 2.4) is heated with 50 % sodium hydroxide at 180 °C for 15 h in an autoclave [7]. After dilution with water, the product is salted out as the monosodium salt and purified by washing with brine.

Uses. 1-Hydroxynaphthalene-3,6-disulfonic acid is used as a coupling component for azo dyes, e.g., C.I. Acid Red 7 (**78**).

78

1-Hydroxynaphthalene-3,8-disulfonic acid [*117-43-1*] (**79**) (8-hydroxynaphthalene-1,6-disulfonic acid), epsilon acid, $C_{10}H_8O_7S_2$, M_r 304.3: the sodium salt crystallizes as the hexahydrate and is readily soluble in water.

Alkali fusion at 200 °C gives 1,8-dihydroxynaphthalene-3-sulfonic acid and amination with ammonia and ammonium chloride at 170 °C gives 6,8-diaminonaphthalene-1-sulfonic acid. Diazo coupling takes place in the 2-position and bromination in the 4-position. The 1,8-sultone is formed on dehydration with concentrated sulfuric acid.

Production. The acid sodium salt of 1-aminonaphthalene-3,8-disulfonic acid (Section 6.2) is hydrolyzed by heating with water under pressure at 180 °C.

Uses. Epsilon acid is used as a coupling component for azo dyes, e.g., C.I. Direct Red 47 (**80**).

79

80

1-Hydroxynaphthalene-4,7-disulfonic acid [*6361-37-1*] (**81**) (4-hydroxynaphthalene-1,6-disulfonic acid), D(Dahl's)acid, $C_{10}H_8O_7S_2$, M_r 304.3: its alkali-metal salts are readily soluble in water. Boiling with 65 % sulfuric acid results in desulfonation and formation of 1-hydroxynaphthalene-7-sulfonic acid (**72**). Diazo coupling and nitrosation take place in the 2-position.

Production. 1-Aminonaphthalene-4,7-disulfonic acid (Section 6.2) is heated with sodium bisulfite under conditions similar to those described for the production of 1-hydroxynaphthalene-4-sulfonic acid (**47**) from sodium naphthionate (see Section 4.2). High yields of **81** have been claimed via sulfonation of 1-(dichlorophosphinyloxy)naphthalene (1-naphthol + $POCl_3$) [40].

81

1-Hydroxynaphthalene-4,8-disulfonic acid [*117-56-6*] (**83**) (4-hydroxynaphthalene-1,5-disulfonic acid), Schollkopf's acid, delta acid, oxy Chicago acid, $C_{10}H_8O_7S_2$, M_r 304.3: the sodium salt is readily soluble in water, but the barium salt is only sparingly soluble. Cold 5 % oleum dehydrates **83** to the sultone **82**, whereas with hot 25 % oleum it undergoes sulfonation to give 1-hydroxynaphthalene-2,4,8-trisulfonic acid. Amination (Bucherer) gives 1-aminonaphthalene-4,8-disulfonic acid and caustic fusion gives 1,8-dihydroxynaphthalene-4-sulfonic acid. Diazo coupling and nitrosation take place in the 2-position.

Production. 1-Hydroxynaphthalene-8-sulfonic acid-1,8-sultone (**73**) (Section 4.2) is heated with sulfuric acid at 80 – 90 °C. The reaction mixture is then quenched by pouring into concentrated brine, whereby the sodium salt of **82** crystallizes. After isolation, this intermediate is hydrolyzed by heating with aqueous sodium carbonate and the product is isolated as its sodium salt after cooling.

73 **82** **83**

Uses. Delta acid is used as a coupling component for azo dyes, e.g., C.I. Acid Blue 169.

4.5. 2-Hydroxynaphthalenedisulfonic Acids

2-Hydroxynaphthalene-3,6-disulfonic acid [*148-75-4*] (**54**) (3-hydroxynaphthalene-2,7-disulfonic acid), R acid, $C_{10}H_8O_7S_2$, M_r 304.3, is readily soluble in water and ethanol. Although the sodium salt (R salt) is soluble in water, it can be precipitated by sodium chloride. The barium salt is sparingly soluble in cold water but is 8 % soluble in boiling water. Whereas sulfonation with 20 % oleum yields 2-hydroxynaphthalene-3,6,8-trisulfonic acid (**56**), the reaction with Na_2SO_3–MnO_2 gives 2-hydroxy-1,3,6-trisulfonic acid. Alkali fusion with sodium hydroxide gives 2,3-dihydroxynaphthalene-6-sulfonic acid and some 2,3-dihydroxynaphthalene. Amination (Bucherer) produces

2-aminonaphthalene-3,6-disulfonic acid. Diazo coupling and nitrosation take place in the 1-position.

Production. 2-Naphthol is heated in excess 98 % sulfuric acid to 60 °C, and anhydrous sodium sulfate is added [7]. The mixture is then heated for 24 h at 105 °C, 12 h at 110 °C, and 12 h at 120 °C before being diluted with more sulfuric acid and quenched in water. Sodium chloride is added at 60 °C, and the mixture is cooled slowly to 30 °C with crystallization of the product as its sodium salt. The isolated yield is 68 %, and the product contains about 3 % of Schaeffer's salt as the major impurity. Alternatively, R salt may be recovered as a byproduct from the G acid process (see page 22). Further purification may be effected via the aniline salt [41].

Uses. The so-called R acid is used as a coupling component for a wide range of azo colorants, e.g., C.I. Mordant Red 9, C.I. Pigment Red 60, C.I. Acid Red 27, and C.I. Food Red 9 (**84**).

84

The aluminum salt of R acid has been used as an astringent and antiseptic (Alumnol).

This acid is an intermediate in the manufacture of 2-aminonaphthalene-3,6-disulfonic acid and 2,3-dihydroxynaphthalene-6-sulfonic acid.

2-Hydroxynaphthalene-3,7-disulfonic acid [*6361-38-2*] (**85**) (3-hydroxynaphthalene-2,6-disulfonic acid), $C_{10}H_8O_7S_2$, M_r 304.3: the alkali-metal salts of **85** are readily soluble in water, but its barium salt is only sparingly soluble even at 100 °C. Sulfonation with 20 % oleum at 85 °C gives mainly 2-hydroxynaphthalene-1,3,7-trisulfonic acid. Amination yields 2-aminonaphthalene-3,7-disulfonic acid, and caustic fusion yields 2,7-dihydroxynaphthalene-3-sulfonic acid. Diazo coupling takes place in the 1-position.

Production. 2-Hydroxynaphthalene-7-sulfonic acid (Section 4.3) is heated at 120 °C with concentrated sulfuric acid for 12 h, the mixture is poured into water, and the product is separated after liming out.

85

2-Hydroxynaphthalene-5,7-disulfonic acid [*575-05-3*] (**68**) (6-hydroxynaphthalene-1,3-disulfonic acid), $C_{10}H_8O_7S_2$, M_r 304.3, and its alkali-metal salts are readily soluble in water. Diazo coupling takes place in the 1-position.

Production. 2-Aminonaphthalene-5,7-disulfonic acid (Section 6.2) is heated with 5 % sulfuric acid for 15 h at 185 °C under pressure [7]. After liming out and removal of ammonia and calcium ions, the product is obtained as a solution of the sodium salt for further use.

Uses. The acid has some use as an azo coupling component and as an intermediate in the production of 2,5-dihydroxynaphthalene-7-sulfonic acid.

2-Hydroxynaphthalene-6,8-disulfonic acid [*118-32-1*] (**55**) (7-hydroxynaphthalene-1,3-disulfonic acid), G acid, $C_{10}H_8O_7S_2$, M_r 304.3: most salts of **55** are more readily soluble in water than those of R acid, with the notable exception of the potassium salt. Sulfonation with 20 % oleum at 100 °C yields 2-hydroxynaphthalene-3,6,8-trisulfonic acid (**56**). Diazo coupling takes place in the 1-position, although the reaction is sluggish, as in the case of 2-hydroxynaphthalene-8-sulfonic acid.

Production. 2-Naphthol is added to 98 % sulfuric acid at 40 °C. Then, 20 % oleum is added over 6 h and the temperature is allowed to rise to 60 °C. The reaction is completed by heating for a further 16 h at 60 °C followed by 15 h at 80 °C. After the reaction mixture has been poured into water, potassium chloride is added to the hot solution and the batch is cooled slowly to 35 °C before filtering off the crystalline dipotassium salt of G acid and carefully washing out any residual R salt; the yield is 60 %. In addition, R salt can be recovered from the filtrate in 12 % yield after conversion to its sodium salt.

Uses. The G acid is aminated (Bucherer reaction) to give 2-aminonaphthalene-6,8-disulfonic acid and subjected to caustic fusion at 200 °C to

yield 2,8-dihydroxynaphthalene-6-sulfonic acid (a precursor of γ acid). It is also used as a coupling component for a wide range of azo colorants, e.g., C.I. Acid Orange 10, C.I. Acid Red 187, and C.I. Food Red 7 (**86**).

86

4.6. Hydroxynaphthalenetrisulfonic Acids

1-Hydroxynaphthalene-3,6,8-trisulfonic acid [*3316-02-7*] (**69**) (8-hydroxynaphthalene-1,3,6-trisulfonic acid), oxy Koch acid, $C_{10}H_8O_{10}S_3$, M_r 384.3, and its alkali-metal salts are readily soluble in water. Amination at 170 °C gives 1-aminonaphthalene-3,6,8-trisulfonic acid. Diazo coupling takes place in the 2-position.

Production. 1-Aminonaphthalene-3,6,8-trisulfonic acid (Section 6.3) is heated with dilute sulfuric acid at 180 °C under pressure for 20 h [7]. After the mixture is run into excess sodium hydroxide solution, ammonia is removed by heating and the total liquor is used directly for the production of chromotropic acid (Section 4.7) by caustic fusion.

2-Hydroxynaphthalene-3,6,8-trisulfonic acid [*6259-66-1*] (**56**) (7-hydroxynaphthalene-1,3,6-trisulfonic acid), $C_{10}H_8O_{10}S_3$, M_r 384.3, and its alkali-metal salts are readily soluble in water; nevertheless, the sodium salt is obtainable by salting out. Amination at 240 °C gives 2-aminonaphthalene-3,6,8-trisulfonic acid. Alkali fusion gives a mixture of dihydroxynaphthalenedisulfonic acids and finally 4,6,7-trihydroxynaphthalene-2-sulfonic acid. Diazo coupling occurs slowly in the 1-position.

Production. 2-Naphthol is heated with sulfuric acid monohydrate at 115 °C for 3 h. The reaction mixture is cooled and 65 % oleum is added, followed by heating at 115 °C for 12 h [7], after which it is poured into water. Salt is then added to the hot solution and the sodium salt of the product crystallizes. Further purification is effected by redissolving in water and salting out.

Uses. The acid is used as an azo coupling component in, e.g., C.I. Solvent Red 31 (the dicyclohexylamine salt of **87**).

87

4.7. Dihydroxynaphthalenesulfonic Acids

Although many isomers are known [5], only the four compounds that have been used industrially (mainly as azo coupling components) are described. All are obtained in high yield by selective fusion processes.

4,5-Dihydroxynaphthalene-1-sulfonic acid [*83-65-8*] (**60**) (1,8-dihydroxynaphthalene-4-sulfonic acid), dioxy Chicago acid, dioxy S acid, $C_{10}H_8O_5S$, M_r 240.2, is sparingly soluble in water, but the sodium salt is readily soluble. Heating with dilute sulfuric acid at 150 °C gives 1,8-dihydroxynaphthalene (Section 3.3).

Production. 1-Hydroxynaphthalene-4,8-disulfonic acid (Section 4.4) is heated with 82 % caustic soda liquor for 3 h at 235 °C [7]. The melt is poured into excess hydrochloric acid and sulfur dioxide is expelled. After cooling, the product is filtered off and washed with brine; the yield is 83 %.

4,6-Dihydroxynaphthalene-2-sulfonic acid [*6357-93-3*] (**61**) (2,8-dihydroxynaphthalene-6-sulfonic acid), dioxy G acid, $C_{10}H_8O_5S$, M_r 240.2, is readily soluble in water, but the sodium salt is less so and can be salted out.

Production. The potassium salt of 2-hydroxynaphthalene-6,8-disulfonic acid (Section 4.4) is heated with 70 % caustic liquor for 3 h at 230 °C and then at 240 °C for completion of the reaction. The melt is diluted with water and poured into excess hydrochloric acid. After sulfur dioxide has been expelled, salt is added and

the batch is cooled to precipitate the product, which is filtered off and washed with brine; the yield is 80 %.

Uses. Dioxy G acid is used as an intermediate in the production of 2-amino-8-hydroxynaphthalene-6-sulfonic acid (γ acid) and its N-substituted derivatives by means of the Bucherer reaction with ammonia or primary amines. It is also used as a coupling component for azo dyes such as C.I. Mordant Black 56 (**88**).

88

4,7-Dihydroxynaphthalene-2-sulfonic acid [*6357-94-4*] (**62**) (2,5-dihydroxynaphthalene-7-sulfonic acid), dioxy J acid, $C_{10}H_8O_5S$, M_r 240.2, is readily soluble in water; its sodium salt is much less soluble and is easily salted out. Amination with NH_3–$NaHSO_3$ yields J acid (Section 8.2).

Production. 2-Hydroxynaphthalene-5,7-disulfonic acid (Section 4.4) is heated with aqueous NaOH – KOH for 5 h at 175 °C [7]. The melt is poured into water and acidified with hydrochloric acid, and the precipitated solid is filtered off and washed with brine; the yield is 80 %.

Uses. Although not used as a precursor for J acid itself, **62** can be used advantageously for the production of some N-substituted J acids.

6,7-Dihydroxynaphthalene-2-sulfonic acid [*92-27-3*] (**63**) (2,3-dihydroxynaphthalene-6-sulfonic acid), dioxy R acid, $C_{10}H_8O_5S$, M_r 240.2, is readily soluble in water. The sodium salt is sparingly soluble in cold water but readily soluble in hot water. Heating with dilute sulfuric acid at 190 °C gives 2,3-dihydroxynaphthalene (Section 3.3).

Production. 2-Hydroxynaphthalene-3,6-disulfonic acid (Section 4.4) is heated with 70 % caustic soda liquor for 4 h at 270 °C, after which the reaction mixture is diluted with water and poured into excess hydrochloric acid [7]. The precipitated product is filtered off and washed with brine; the yield is 90 %.

4.8. Dihydroxynaphthalenedisulfonic Acids

Although many isomers are known [5], only the three significant ones are described here. All are obtained by selective fusion processes, although yields are lower than for the monosulfonic acids (Section 4.7).

3,5-Dihydroxynaphthalene-2,7-sulfonic acid [*81344-22-1*] (**64**), A acid, $C_{10}H_8O_8S_2$, M_r 320.3.

Production. 2-Hydroxynaphthalene-3,6,8-trisulfonic acid (Section 4.6) is heated with caustic soda liquor at 240 °C, and the melt is poured into water and neutralized. Careful addition of salt precipitates the product and leaves the more soluble 2,3-dihydroxy byproduct in solution.

3,6-Dihydroxynaphthalene-2,7-disulfonic acid [*23894-07-7*] (**65**), $C_{10}H_8O_8S_2$, M_r 320.3.

Production. 2-Hydroxynaphthalene-3,6,7-trisulfonic acid is heated with 66 % caustic soda liquor at 200 – 300 °C and the product worked up by dilution, neutralization, and salting out.

4,5-Dihydroxynaphthalene-2,7-disulfonic acid [*148-25-4*] (**66**) (1,8-dihydroxynaphthalene-3,6-disulfonic acid), chromotropic acid, $C_{10}H_8O_8S_2$, M_r 320.3: the disodium salt is readily soluble in water. Alkali fusion yields 1,3,8-trihydroxynaphthalene-6-sulfonic acid. Diazo coupling occurs in the 3- and 6-positions.

Production. 2-Hydroxynaphthalene-3,6,8-trisulfonic acid total liquor (Section 4.6) is concentrated and heated with caustic soda liquor to 158 °C for 20 – 30 h [7]. The melt is diluted with water and poured into excess hydrochloric acid. Salt is added, sulfur dioxide expelled, and the mixture cooled to precipitate the product as the disodium salt in 88 % yield.

An alternative process is based on direct fusion (caustic liquor at 228 °C under pressure) of 1-aminonaphthalene-3,6,8-trisulfonic acid (Section 6.3) to chromotropic acid without isolating the intermediate oxy Koch acid [7].

Uses. Chromotropic acid is used as an analytical reagent and as a coupling component for a wide range of azo dyes, e.g., C.I. Acid Violet 6, C.I. Mordant Blue 13, and C.I. Direct Blue 84 (the dicopper complex of demethylated **89**).

89

5. Aminonaphthalenes

The two general methods for the synthesis of monoamino- and diaminonaphthalenes are reduction or hydrogenation of the corresponding nitronaphthalene derivative, and amination (Bucherer reaction) of the corresponding hydroxynaphthalene derivative. Although the former method is analogous to the general method for substituted anilines, the Bucherer reaction is not applicable to phenols.

90

91

5.1. Naphthylamines

1-Naphthylamine [*134-32-7*] (**90**), 1-naphthaleneamine, 1-aminonaphthalene, α-naphthylamine, $C_{10}H_9N$, M_r 143.18, *mp* 50 °C, *bp* 301 °C, pK_a 10.0, d_4^{20} 1.131, sublimes and is steam volatile. It crystallizes from aqueous ethanol as colorless needles, which slowly turn red on exposure to air. Solubility in water is 0.16 % at 20 °C. It behaves as a typical primary aromatic amine in forming salts with strong acids (but not with acetic or benzoic acid) and readily forming *N*-acyl derivatives.

1-Naphthylamine couples with diazo compounds in the 4-position, with up to 10 % byproduct being formed by coupling in the 2-position.

Oxidation of 1-naphthylamine salts with iron(III) chloride in aqueous solution gives an insoluble blue-violet compound, whereas oxidation with chromic acid yields 1,4-naphthoquinone and phthalic acid. Reduction with Na – NaOEt leads to the 5,6,7,8-tetrahydro compound, which can also be formed together with the 1,2,3,4-tetrahydro derivative by catalytic hydrogenation. Sulfonation gives a complex mixture of mono-, di-, and trisulfonic acids.

Production. Naphthalene is nitrated with H_2SO_4–HNO_3 at 50 – 60 °C [7]. The crude product (*mp* 52 °C) is separated, washed with hot water, and further purified by crystallization or sweating (draining off the lower melting isomer) to remove 2-nitronaphthalene (3 %) and traces of 2,4-dinitronaphthalene. Purified 1-nitronaphthalene was traditionally reduced with iron in boiling dilute hydrochloric acid, but modern plants use hydrogenation with a nickel catalyst. The 1-naphthylamine produced is further purified by distillation under vacuum. The content of 2-naphthylamine in the commercial product is specified at <10 ppm.

Uses. A large proportion of the 1-naphthylamine produced is converted to 1-naphthol (Section 3.1). Other major uses are in the production of aminonaphthalenesulfonic acid dye intermediates (Chap. 6) and as a component of azo dyes. In the latter, use as a coupling component, followed by diazotization and further coupling of the resulting aminoazo compound, predominates, e.g., for C.I. Acid Blue 113 (**92**).

92

Other important derivatives are C.I. Solvent Brown 1, C.I. Acid Red 20, C.I. Direct Brown 208, and C.I. Mordant Black 68.

The rubber antioxidant 1-phenylaminonaphthalene (**24**) can be obtained from 1-naphthol (Section 3.1). However, because the latter is now manufactured from 1-naphthylamine, it is more convenient to manufacture **24** directly from 1-naphthylamine and aniline by a vapor-phase catalytic process (alumina gel, 300 °C). *N*-Alkyl-1-naphthylamines are usually manufactured from 1-naphthol; for example, *N*-ethyl-1-naphthylamine is of particular importance as an intermediate for Victoria Blues.

The selective preemergence herbicide naptalam [*132-66-1*] (**93**), *N*-1-naphthylphthalamic acid, is produced by acylation of **90** by heating with an equimolar quantity of phthalic anhydride in a solvent such as xylene [42].

The rodenticide ANTU [*86-88-4*] (**94**), 1-naphthalenethiourea, is manufactured from 1-naphthylamine by reaction with thiocyanate ion in aqueous acid solution. The elimination of ammonia from **94** by heating in chlorobenzene is a convenient method for producing 1-naphthyl isothiocyanate.

Acylation of *N*-methyl-1-naphthylamine with fluoroacetyl chloride yields the insecticide and acaricide Nissol [*5903-13-9*] (**95**). An improved process is based on reaction of the corresponding chloroacetamido derivative with potassium fluoride in a glycol solvent [43].

93 **94** **95**

Toxicology [14], [44]. 1-Naphthylamine is toxic to humans by inhalation or skin absorption and is classed as a potential carcinogen. Samples are often contaminated with highly carcinogenic 2-naphthylamine, which confused many earlier results. Although frequently quoted, data on toxicity to animals are inconclusive compared with those available for the 2-isomer.

The metabolism of 1-naphthylamine in animals and humans has been studied, with a variety of results. *N*-(1-naphthyl)hydroxylamine and *N*-hydroxy-1-naphthylacetamide appear to be key metabolic products, in contrast to the behavior of 2-naphthylamine.

Use in the United Kingdom is controlled by the Carcinogenic Substances Regulations of 1967 and in the United States by the Federal Register of Carcinogens (1973).

2-Naphthylamine [*91-59-8*] (**91**), 2-aminonaphthalene, 2-naphthaleneneamine, *β*-naphthylamine, $C_{10}H_9N$, M_r 143.18, *mp* 112 °C, *bp* 306 °C, d_4^{98} 1.061 is steam volatile and is soluble in hot water, ethanol, and ether. It crystallizes from aqueous ethanol as white crystals that turn red on exposure to light and air.

Oxidation with hypochlorite, lead dioxide, or air in UV light gives dibenzophenazine. Reduction with sodium in amyl alcohol or catalytic hydrogenation gives mainly 2-aminotetralin. Substition reactions (e.g., halogenation) occur first in the 1-position unless the amino group is protonated, in which case substituents enter the 5- and 8-positions.

Production. 2-Naphthol is heated with an $NH_4OH - NH_4HSO_3$ mixture at 180 °C for 20 h, and the molten amine is separated after basification and removal of excess ammonia. After being dried, the oil is distilled under vacuum. Production of 2-naphthylamine ceased worldwide in the 1950s.

Uses. Historically, 2-naphthylamine was an important colorant intermediate. Two examples are solvent sulfonation to Tobias acid (Section 6.1) and formation of Naphthol BN (**96**). Until 1950 the latter was the most important azoic coupling component after Naphthol AS (**44**). After production of 2-naphthylamine ceased, Naphthol BN was prepared for a time via Tobias acid and desulfonation.

96

Although *N*-phenyl-2-aminonaphthalene (**32**) was produced originally from 2-naphthylamine, all production of this antioxidant is now based on 2-naphthol (Section 3.2).

Toxicology [14], [44]. 2-Naphthylamine is a human carcinogen that leads predominately to formation of tumors in the epithelium of the bladder. The conclusive epidemiological studies on humans are backed up by a wealth of animal data. However, although a proven carcinogen in mouse, hamster, dog, and monkey, 2-naphthylamine exhibits little, if any, carcinogenicity in rat or rabbit. Several metabolic pathways have been identified, but the main one involves N-hydroxylation followed by rearrangement to 2-amino-1-hydroxynaphthalene. Only the former is a proven animal carcinogen.

Measurement of 2-naphthylamine impurity levels requires sophisticated analysis. For example, 22 ng per cigarette was measured by GLC of the *N*-pentafluoropropionyl derivative. The levels found were considered to be biologically insignificant [45].

Use in the United Kingdom is prohibited under the Carcinogenic Substances Regulations of 1967; in the United States, by the Environmental Protection Agency; and in all industrialized nations, by comparable regulatory authorities.

Although *N*-phenyl-2-aminonaphthalene (PBN, **32**) has been classed as a potential carcinogen, its toxicity is more likely to be due to the presence of primary amines as impurities.

5.2. Naphthalenediamines

All ten of the isomeric diamines are known [5]. Table 5 lists their melting points, CAS registry numbers, and solubilities. Only the 1,5- and 1,8-isomers are readily available and of commercial significance.

Table 5. Physical properties of naphthalenediamines

Isomer	CAS re gistry no.	*mp*, °C	Solubility
1,2	[*938-25-0*]	98	soluble in hot water, alcohol, and ether
1,3	[*24824-28-0*]	96	
1,4	[*2243-61-0*]	120	slightly soluble in hot water
1,5	[*2243-62-1*]	189	soluble in hot water and alcohol
1,6	[*2243-63-2*]	78	soluble in hot water and alcohol
1,7	[*2243-64-3*]	117	soluble in alcohol
1,8	[*479-27-6*]	66	soluble in alcohol and ether
2,3	[*771-97-1*]	199	soluble in alcohol and ether
2,6	[*2243-67-6*]	220	slightly soluble in alcohol and ether
2,7	[*613-76-3*]	166	

1,5-Naphthalenediamine [*2243-62-1*] (**97**), 1,5-diaminonaphthalene, Alphamin, $C_{10}H_{10}N_2$, M_r 158.2: oxidation of **97** with iron(III) chloride in water produces a blue-violet color. Treatment with boiling aqueous sodium bisulfite followed by addition of alkali gives a mixture of 1-amino-5-hydroxynaphthalene and 1,5-dihydroxynaphthalene. Sulfonation (5 % oleum, 100 °C) gives 1,5-diaminonaphthalene-2-sulfonic acid, and nitration in acetic acid produces 2,4,6,8-tetranitro-1,5-diaminonaphthalene. Coupling with diazo compounds takes place in the 2-position; reduction of the resulting azo compound with $SnCl_2$–HCl produces 1,2,5-triaminonaphthalene.

Production. 1-Nitronaphthalene can be nitrated further to give a 40 : 60 mixture of 1,5- and 1,8-dinitronaphthalenes. Similar results are obtained by direct nitration of naphthalene with H_2SO_4–HNO_3 under careful control of temperature over the range 40 – 80 °C. Although separation of the isomers by fractional crystallization or solvent extraction [46] is usually carried out at this stage, the mixed isomers can also be reduced and the resulting diamines separated. Reduction of the dinitronaphthalenes is achieved by treatment of a nonaqueous solution with iron or hydrogen in the presence of a catalyst.

An alternative process for 1,5-naphthalenediamine involves amination of 1,5-dihydroxynaphthalene with ammonia and ammonium bisulfite. Although less efficient on a stage basis it offers an economical alternative to nitration and reduction if the 1,8-naphthalenediamine (**98**) is not also required.

Uses. 1,5-Naphthalenediamine is an intermediate in the manufacture of naphthalene-1,5-diisocyanate [*3173-72-6*] (**99**), which is used for specialty polyurethane polymers. It has only limited use as a dye intermediate.

Toxicity. Like 1-naphthylamine, 1,5-naphthalenediamine is classed as having limited carcinogenicity in animals [14], [44].

1,8-Naphthalenediamine [*479-27-6*] (**98**), 1,8-diaminonaphthalene, Deltamin, $C_{10}H_{10}N_2$, M_r 158.2, turns brown in air even in the ab-

sence of light. Its solutions give a brown precipitate on addition of iron(III) chloride. Treatment with boiling aqueous sodium bisulfite followed by addition of alkali gives 8-amino-1-hydroxynaphthalene. Sulfonation takes place in the 4-position. Coupling with azo compounds also occurs in the 4-position, but in almost neutral solution 4,5-bis coupling can occur. The resulting bisazo compound is reduced with $SnCl_2$–HCl to give 1,4,5,8-tetraaminonaphthalene.

Production. Reduction of 1,8-dinitronaphthalene is carried out with iron and acetic acid in xylene or by catalytic hydrogenation.

Uses. 1,8-Naphthalenediamine has minor use as an antioxidant for lubricating oils and as an analytical reagent for the detection of selenium and nitrites.

Treatment of a solution of the hydrochloride of **98** with acetic anhydride yields methylperimidine (**100**), a colorant intermediate. Most important are the phthaloperinone pigments obtained by reaction of **98** with substituted phthalic anhydrides [47]. The parent product (**101**) is a lightfast, heat-stable orange dye for poly(methyl methacrylate) and is used to color the covers for automobile indicator lights.

100 **101**

6. Aminonaphthalenesulfonic Acids

Many aminonaphthalenesulfonic acids are important intermediates either for the direct production of azo dyes or for conversion to more highly substituted intermediates for azo dyes. About 24 products in this group have been made industrially, and many of them are still commercially available and referred to by code names (Table 1). The most important are the C, Peri, and Laurent's acids [17]. Only those isomers that have a history of large-scale use are dealt with here on an individual basis. Many other isomers are also obtainable and may be of potential present or future interest [5].

Because in usage this group of products is considered to be derived from 1- and 2-naphthylamines they are dealt with on this basis rather than as amino derivatives of naphthalenesulfonic acids. The latter is the IUPAC convention, and these names are given in parentheses alongside alternative trivial names.

6.1. Production and Properties

Production depends on four main routes to achieve the required substitution patterns. As with most naphthalene substitution reactions, isomeric mixtures often arise so that isomer separation or purification to remove unwanted byproducts is required. High-performance liquid chromatography is an essential analytical tool for following separations and assessing the purity of products.

Sulfonation of Naphthylamines. Sulfonation of 1-naphthylamine gives a variety of products depending on conditions (Fig. 3). Further sulfonation of the separated and isolated primary products leads to di- and trisulfonic acids.

Although 2-naphthylamine can be sulfonated to give a range of isomeric mono- and disulfonic acids, this method is not discussed here because use of this starting material is now prohibited.

Nitration – Reduction of Naphthalenesulfonic Acids. Both naphthalene-1-sulfonic acid and 2-sulfonic acid undergo nitration to give separable mixtures of 5- and 8-nitro compounds, which are isolated and reduced to the corresponding aminonaphthalenesulfonic acids (Fig. 4).

Naphthalene-1,5-disulfonic acid is nitrated to give the 3-nitro derivative, which is reduced to 2-aminonaphthalene-4,8-disulfonic acid (**118**). Other available disulfonic acid isomers are similarly mononitrated and reduced to aminonaphthalenedisulfonic acids (see. Fig. 5).

Amination of Hydroxynaphthalenesulfonic Acids. The Bucherer reaction is most readily applicable to 2-hydroxynaphthalenemono- and disulfonic acids, as shown in the following examples.

Figure 3. Sulfonation of 1-naphthylamine

Figure 4. Nitration – reduction of naphthalenesulfonic acids

Figure 5. Nitration – reduction of naphthalenedisulfonic acids

Desulfonation. As with certain hydroxynaphthalenedi- and trisulfonic acids (Section 4.1), selective desulfonation is exploited with aminonaphthalenedi- and trisulfonic acids. Heating with dilute sulfuric acid is the standard process; sulfonic acid groups adjacent to the amino group are usually labile. A different mechanism may apply when sodium amalgam is required in the case of peri-desulfonation, e.g., with **116** (see top of the next page).

Although many naphthalene derivatives exhibit UV fluorescence in solution, aminonaphthalenesulfonic acids are notable in commonly showing solution fluorescence in daylight. The fluorescent color is in the green – blue – violet area [15], with no obvious correlation between color and structure. Nevertheless, an attempt has been made to systematize the spectral identification of substituted naphthalenesulfonic acids as a contribution to the structural determination of azo dyes after reductive scission [48].

The fluorescence has been exploited with 5-dimethylamino-1-naphthalenesulfonyl chloride [*605-65-2*] (dansyl chloride), which is reacted with amino acids for labeling purposes in protein sequencing.

6.2. 1-Aminonaphthalenesulfonic Acids

1-Aminonaphthalene-2-sulfonic acid [*81-06-1*] (**102**), *ortho*-naphthionic acid, $C_{10}H_9NO_3S$, M_r 223.24, *mp* 262 – 265 °C (decomp.), is sparingly soluble in cold water but dissolves in hot water to give a 3 % solution. The sodium salt is more readily soluble in water (1.7 % at 20 °C and 10 % at 100 °C). The calcium salt is similarly soluble, but the barium salt is almost insoluble.

Production. 1-Naphthylamine (Section 5.1) can be sulfonated by heating with sulfuric acid at 180 – 185 °C, but the transient intermediate naphthalene-1-sulfamic acid is best prepared from 1-aminonaphthalene-4-sulfonic acid (naphthionic acid) [7]. When sodium naphthionate is heated in a solvent such as *o*-dichlorobenzene or xylene at 225 °C, thermal rearrangement occurs to give the 1,2-isomer in high yield.

1-Aminonaphthalene-3-sulfonic acid [*134-54-3*] (**125**) (4-aminonaphthalene-2-sulfonic acid), $C_{10}H_9NO_3S$, M_r 223.24, is only sparingly soluble in water, but its alkali-metal salts are readily soluble. Sulfonation with 20 % oleum yields 1-aminonaphthalene-3,5-disulfonic acid, and heating with water under pressure gives 1-hydroxynaphthalene-3-sulfonic acid, which can also be obtained by diazotization and acid hydrolysis of **125**.

Production. 1-Aminonaphthalene-3,8-disulfonic acid (Section 6.4) in dilute sodium hydroxide solution is pumped at 40 °C through a special reactor that effects contact with continuously produced sodium amalgam [7]. The resulting liquor is used directly for production of 1-hydroxynaphthalene-3-sulfonic acid (Section 4.2).

1-Aminonaphthalene-4-sulfonic acid [*84-86-6*] (**103**) (4-aminonaphthalene-1-sulfonic acid), naphthionic acid, Piria's acid, $C_{10}H_9NO_3S$, M_r 223.24, is sparingly soluble in water (0.25 % at 100 °C), but the sodium, potassium, calcium, and barium salts are all readily soluble.

Chlorination of **103** with copper(II) chloride produces 4-chloro-1-aminonaphthalene, whereas the action of chlorine on an aqueous sulfuric acid solution gives 2,3-dichloro-1,4-naphthoquinone. High-temperature bromination gives 2,4-dibromo-1-aminonaphthalene, whereas vigorous nitration yields 2,4-dinitro-1-hydroxynaphthalene. Sulfonation with 25 %

oleum gives 1-aminonaphthalene-4,6- and 4,7-disulfonic acids, whereas prolonged heating with sulfuric acid at 130 °C leads to 1-aminonaphthalene-5- and 6-sulfonic acids. Hydrolysis of the 1-amino group to give 1-hydroxynaphthalene-4-sulfonic acid is best achieved by a reverse-Bucherer reaction but also results from prolonged heating with 50 % sodium hydroxide.

Production. Naphthionic acid was first prepared by PIRIA by heating 1-nitronaphthalene with ammonium sulfite; however, the formation of 1-aminonaphthalene-2,4-disulfonic acid and other byproducts makes this route unattractive for large-scale production. Although it can also be prepared by direct sulfonation of 1-naphthylamine, it is more conveniently produced by a solvent-bake process [6]. 1-Naphthylamine is dissolved in *o*-dichlorobenzene and H_2SO_4 (molar ratio 1 : 1) added to form a suspension of the sulfate. After being heated gradually to 180 °C, the reaction is completed by maintaining this temperature until all the water of reaction has been distilled off with solvent recycle. The product is extracted from the final mixture by addition to aqueous sodium carbonate solution. After separation, the aqueous layer is steam distilled to remove residual solvent, and the product is salted out, filtered, and washed with brine to give sodium naphthionate as a paste in 90 % yield [7].

Uses. Naphthionic acid is used as an intermediate in the production of 1-hydroxynaphthalene-4-sulfonic acid, 1-aminonaphthalene-2-sulfonic acid, and 1-aminonaphthalene-4,6- and 4,7-disulfonic acids. Use as a diazo component has been previously described, e.g., C.I. Food Red 3 (**71**), C.I. Food Red 7 (**86**), C.I. Food Red 9 (**84**), and C.I. Acid Red 25 (**77**).

1-Aminonaphthalene-5-sulfonic acid [*84-89-9*] (**104**) (5-aminonaphthalene-1-sulfonic acid), Laurent's acid, L acid, Purpurin acid, $C_{10}H_9NO_3S$, M_r 223.24, crystallizes from hot water as needles of the monohydrate. The alkali-metal salts are all readily soluble in water.

Bromination yields the 2,4-dibromo derivative, vigorous nitration gives 2,4-dinitro-1-hydroxynaphthalene, and sulfonation results in 1-aminonaphthalene-2,5,7-trisulfonic acid. 1-Hydroxynaphthalene-5-sulfonic acid is obtained by heating **104** with aqueous bisulfite (reverse-Bucherer reaction) or via the diazo compound. Caustic fusion produces 5-amino-1-hydroxynaphthalene (Chap. 7). Coupling with diazo compounds takes place in the 2-position.

Production. Laurent's acid is coproduced with Peri acid as the minor component of a 5:2 isolated product ratio.

Uses. Laurent's acid is used as an intermediate for 1-hydroxynaphthalene-5-sulfonic acid, 5-amino-1-naphthol, 1-aminonaphthalene-5,7-disulfonic acid, and 8-amino-4-hydroxynaphthalene-2-sulfonic acid.

1-Aminonaphthalene-6-sulfonic acid [*119-79-9*] (**105**) (5-aminonaphthalene-2-sulfonic acid), 1,6-Cleve's acid, $C_{10}H_9NO_3S$, M_r 223.24, crystallizes from boiling water as plates of the dihydrate. Its sodium, potassium, and calcium salts are all readily soluble in water, but the barium salt is only sparingly soluble. Sulfonation with 10 % oleum yields 1-aminonaphthalene-4,6-disulfonic acid. Caustic fusion gives 5-amino-2-hydroxynaphthalene, and Bucherer-type hydrolysis gives 1-hydroxynaphthalene-6-sulfonic acid.

Production. Sulfonation of 1-naphthylamine with concentrated sulfuric acid at 130 °C gives mainly 1-aminonaphthalene-6-sulfonic acid. However, the latter is always made, together with the 1,7-isomer, by nitration of naphthalene-2-sulfonic acid to give the mixed 5- and 8-nitronaphthalene-2-sulfonic acids follwed by reduction to "mixed Cleve's acids." A β-sulfonation mass (Section 2.2) is diluted with sulfuric acid, then 67.5 % nitric acid is added slowly at 34 °C. After being quenched and neutralized with calcium carbonate, the filtered liquor is reduced by boiling with iron powder, slight acidity being maintained with sulfuric acid. After basification with magnesia the iron residues are filtered off and the filtrate is evaporated until the magnesium salt of the product crystallizes on cooling. Filtration followed by washing with magnesium sulfate gives a 34 % yield of the magnesium salt of 1,6-Cleve's acid. Purification by dissolution in hot water, acidification, and filtration of the free acid while hot reduce the yield to 25 % based on naphthalene.

1-Aminonaphthalene-7-sulfonic acid [*119-28-8*] (**113**) (8-aminonaphthalene-2-sulfonic acid), 1,7-Cleve's acid, $C_{10}H_9NO_3S$, M_r 223.24, is 0.5 % soluble in water at 25 °C and

3 % soluble at 100 °C. The sodium, potassium, calcium, and magnesium salts are readily soluble in water but the barium salt is only sparingly soluble. Sulfonation with oleum at 50 °C gives 1-aminonaphthalene-4,7-disulfonic acid. Alkali fusion gives 8-amino-2-naphthol, and Bucherer-type hydrolysis gives 1-hydroxynaphthalene-7-sulfonic acid.

Production. The filtrate from the production of 1,6-Cleve's acid is acidified to precipitate crude 1,7-Cleve's acid (34 % yield), which can be purified by recrystallization of the sodium salt in an overall yield of 29 % based on naphthalene.

Uses. For many azo dye outlets, isolated mixed Cleve's acid from acidification of the reduction liquor is adequate as an economical component in the production, for example, of C.I. Acid Black 36 (**131**).

131

1-Aminonaphthalene-8-sulfonic acid [*82-75-7*] (**112**) (8-aminonaphthalene-1-sulfonic acid), Peri acid, $C_{10}H_9NO_3S$, M_r 223.24, crystallizes as the monohydrate and is sparingly soluble even in boiling water. The sodium salt is also sparingly soluble in water.

Caustic fusion at 200 °C produces 8-amino-1-naphthol, whereas slow hydrolysis with 10 % sodium hydroxide at 220 – 260 °C yields 1,8-dihydroxynaphthalene. Sulfonation with cold 10 % oleum produces 1-aminonaphthalene-4,8-disulfonic acid, whereas hot concentrated sulfuric acid results in slow isomerization into naphthionic acid.

Production [7]. Naphthalene is converted to naphthalene-1-sulfonic acid (see Section 2.2). The crude sulfonation product is diluted with sulfuric acid, and 67.5 % nitric acid is added slowly at 30 °C to give the 5- and 8-nitro derivatives. The products are converted to the readily soluble magnesium salts by addition of a slurry of dolomite. The reaction mixture is neutralized with chalk and filtered hot. The filtrate is run into a suspension of iron powder in boiling water, which is kept slightly acidic with sulfuric acid. When reduction is complete, dissolved iron is precipitated by addition of magnesia, the iron residues are filtered off while hot, and the resulting liquor is acidified to pH 4.5 with sulfuric acid to give 99 % pure Peri acid in 48 % yield. The filtrates are further acidified to precipitate crude Laurent's acid. This may be purified via its magnesium salt to give a 17 % yield of pure 1,5-isomer.

Uses. Dehydration with phosphorus oxychloride yields naphthosultam (**132**), and diazotization followed by hydrolysis results in naphthosultone (**133**), the intermediate for 1-hydroxynaphthalene-8-sulfonic acid. Diazotization followed by a Sandmeyer cyanide reaction gives 8-cyanonaphthalene-1-sulfonic acid, one of the most industrially important Sandmeyer reaction products because the nitrile forms the lactam, naphthostyril [*130-00-7*] (**134**), upon treatment with concentrated alkali at 185 °C. Hydrolysis of naphthostyril with dilute alkali yields 8-aminonaphthalene-1-carboxylic acid (**135**), which is the key intermediate for production of anthanthrone vat dyes via 1,1′-binaphthyl-8,8′-dicarboxylic acid (**136**).

132 **133** **134**

135 **136** **137**

Although Peri acid couples in the 4-position to form azo dyes, its N-aryl derivatives [e.g., *N*-phenyl (**137**) or *N*-*p*-tolyl] are generally used. These are produced by heating Peri acid with excess amine at 170 °C in the presence of amine hydrochloride. A typical and important acid dye for wool based on **137** is C.I. Acid Blue 113 (**92**). The monoazo compound derived from H acid (C.I. Acid Blue 92) is purified to anazolene sodium (**138**) for diagnostic use as a plasma volume indicator.

138

6.3. 2-Aminonaphthalenesulfonic Acids

2-Aminonaphthalene-1-sulfonic acid [*81-16-3*] (**119**), Tobias acid, $C_{10}H_9NO_3S$, M_r 223.24, is sparingly soluble in water but the sodium salt is readily soluble.

Coupling with diazo compounds takes place in the 1-position with elimination of the sulfonic acid group.

Production. 2-Hydroxynaphthalene-1-sulfonic acid (Section 4.3) is heated with a mixture of ammonia and ammonium sulfite in an autoclave at 150 °C and 1 MPa for 30 h [7]. The reaction mixture is added to a slurry of lime, and excess ammonia is driven off. Inorganic calcium salts are filtered off at 80 °C, and the filtrate is acidified with hydrochloric acid at 40 °C to precipitate Tobias acid in 95 % yield. Care must be taken throughout the process to avoid desulfonation and formation of 2-naphthylamine.

Uses. Sulfonation with oleum gives 2-aminonaphthalene-1,5-disulfonic acid, which can be desulfonated to produce 2-aminonaphthalene-5-sulfonic acid.

Tobias acid is used as a diazo component in acid dyes (e.g., C.I. Acid Yellow 19), red reactive dyes, and pigments such as the important Lithol Reds, [e.g., C.I. Pigment Red 49 (**139**)]. The free acid of **139** is also remarkably insoluble and can be used as a pigment.

139

2-Aminonaphthalene-5-sulfonic acid [*81-05-0*] (**127**) (6-aminonaphthalene-1-sulfonic acid), Dahl's acid, Dressel acid, D acid, $C_{10}H_9NO_3S$, M_r 223.24, crystallizes from water as needles although only 0.4 % soluble at 100 °C. The sodium, calcium, and barium salts are moderately soluble in water.

Bromination in acetic acid gives the 1-bromo derivative. Sulfonation with oleum gives a mixture of 2-aminonaphthalene-5,7-disulfonic acid together with some 1,5-disulfonic acid. Fusion with potassium hydroxide at 260 °C yields 6-amino-1-naphthol.

Production. Tobias acid is added to a mixture of sulfuric acid and oleum, and the reaction is completed by stirring for 12 h at 25 °C. The resulting sulfonation mass, containing mainly 2-aminonaphthalene-1,5-disulfonic acid (**126**), is poured into water and heated at 105 °C for 3 h to desulfonate and precipitate the product which, after cooling, is filtered off; the yield is 95 %.

2-Aminonaphthalene-6-sulfonic acid [*93-00-5*] (**120**) (6-aminonaphthalene-2-sulfonic acid), Bronner acid, $C_{10}H_9NO_3S$, M_r 223.24, crystallizes from water as the monohydrate in plates although only 0.2 % soluble at 100 °C. Sulfonation with 20 % oleum at 20 °C gives a mixture of 1,6- and 6,8-disulfonic acids.

Production. 2-Hydroxynaphthalene-6-sulfonic acid (Section 4.3) is aminated by a Bucherer reaction under conditions similar to those used for Tobias acid.

2-Aminonaphthalene-7-sulfonic acid [*494-44-0*] (**121**) (7-aminonaphthalene-2-sulfonic acid), amido F acid, $C_{10}H_9NO_3S$, M_r 223.24, crystallizes as the monohydrate in needles or prisms although only 0.3 % soluble at 100 °C.

Bromination gives the 1-bromo derivative, caustic fusion results in 7-amino-2-naphthol, and sulfonation with oleum gives a mixture of disulfonic acids.

Production. 2-Hydroxynaphthalene-7-sulfonic acid (Section 4.3) is aminated by a Bucherer reaction under conditions similar to those used for Tobias acid.

2-Aminonaphthalene-8-sulfonic acid [*86-60-2*] (**122**) (7-aminonaphthalene-1-sulfonic acid), Badische acid, $C_{10}H_9NO_3S$, M_r 223.24, crystallizes from water as needles or prisms although only 0.5 % soluble at 100 °C. Alkali-metal salts are quite soluble in water. Caustic fusion yields 7-amino-1-naphthol, sulfonation in the cold with 20 % oleum gives 2-aminonaphthalene-6,8-disulfonic acid, but nitration gives a mixture of products. 2-Aminonaphthalene-8-sulfonic acid reacts with diazo compounds to

form diazoamino compounds rather than coupling to give azo derivatives.

Production. 2-Hydroxynaphthalene-8-sulfonic acid (Section 4.3) is aminated by a Bucherer reaction under conditions similar to those used for Tobias acid.

6.4. 1-Aminonaphthalenedisulfonic Acids

Although preparation of fourteen of the possible isomers has been reported [5], only processes for those seven isomers that have been used as intermediates or dye components are described here.

1-Aminonaphthalene-3,6-sulfonic acid [*6251-07-6*] (**114**) (4-aminonaphthalene-2,7-disulfonic acid), Freund's acid(1,3,6), $C_{10}H_9NO_6S_2$, M_r 303.3, and its salts are readily soluble in water. Caustic fusion results in a mixture of aminonaphtholsulfonic acids, but amination occurs selectively, producing 1,3-diaminonaphthalene-6-sulfonic acid.

Production. Naphthalene is sulfonated with sulfuric acid at 160 °C for 14 h to give a mixture of mainly 2,6- and 2,7-disulfonic acids [7]. The reaction mass is nitrated with H_2SO_4–HNO_3 at 30 °C, poured into water, and limed out. The filtrate is then reduced with iron and hydrochloric acid, and the reduction liquor is worked up to selectively salt out the sodium salt of 1-aminonaphthalene-3,7-disulfonic acid in 17.5 % yield. The filtrates and brine wash are then acidified to precipitate crude 1-aminonaphthalene-3,6-disulfonic acid, which is purified by dissolution in aqueous potassium hydroxide and precipitation with acid; the yield is 35 %.

1-Aminonaphthalene-3,7-disulfonic acid [*6362-05-6*] (**115**) (4-aminonaphthalene-2,6-disulfonic acid), Freund's acid(1,3,7), $C_{10}H_9NO_6S_2$, M_r 303.3, is readily soluble in water, but its salts are less soluble than those of the 1,3,6-isomer. The amino group is hydrolyzed by water at 180 °C to give 1-hydroxynaphthalene-3,7-disulfonic acid. Caustic fusion results in formation of 1-amino-7-hydroxynaphthalene-3-sulfonic acid, and amination gives 1,3-diaminonaphthalene-7-sulfonic acid.

Production. The 1,3,7-acid is produced together with the 1,3,6-isomer [7].

1-Aminonaphthalene-3,8-disulfonic acid [*129-91-9*] (**116**) (8-aminonaphthalene-1,6-disulfonic acid), amino epsilon acid, $C_{10}H_9NO_6S_2$, M_r 303.3, and its sodium salt are very soluble in water, but the barium salt is only sparingly soluble. Reduction with zinc and alkali (or with sodium amalgam) desulfonates **116** to give 1-aminonaphthalene-3-sulfonic acid. The amino group is hydrolyzed by water at 180 °C to give 1-hydroxynaphthalene-3,8-disulfonic acid. Caustic fusion results in 1-amino-8-hydroxynaphthalene-3-sulfonic acid, whereas reaction with 10 % sodium hydroxide at 250 °C produces 1,8-dihydroxynaphthalene-3-sulfonic acid. Amination produces 1,3-diaminonaphthalene-8-sulfonic acid (**149**), but the production of 6,8-di(phenylamino)naphthalene-1-sulfonic acid (diphenyl epsilon acid; **140**) by reaction with aniline is more important.

Production. Naphthalene is sulfonated under conditions that give predominately the 1,6-disulfonic acid. The sulfonation mass is nitrated with H_2SO_4–HNO_3 at 30–40 °C [7]. After addition of dolomite and neutralization with lime, the liquor is reduced with iron and basified with magnesia, and the iron residues are removed. Careful adjustment of temperature and acidity precipitates the product as the acid magnesium salt, which is purified by dissolution in aqueous sodium carbonate and removal of magnesium carbonate; the diacid is precipitated with acid in 32 % overall yield.

Uses. Amino ε acid is used mainly as an intermediate rather than as a color component, but the derived diphenyl ε acid (**140**) is used for safranine dyes such as C.I. Acid Blue 61 (**141**).

140

141

1-Aminonaphthalene-4,6-disulfonic acid [*85-74-5*] (**108**) (4-aminonaphthalene-1,7-disulfonic acid), Dahl's acid II, $C_{10}H_9NO_6S_2$, M_r 303.3, and its alkali-metal salts are soluble in water; the calcium salt is soluble in aqueous ethanol. Caustic fusion at 180 °C yields 1-amino-6-hydroxynaphthalene-4-sulfonic acid, but at higher temperature 4,7-dihydroxynaphthalene-1-sulfonic acid is formed. Sulfonation with 35 % oleum at 80 °C gives 1-aminonaphthalene-2,4,6-trisulfonic acid.

Production. Naphthionic acid is sulfonated with 25 % oleum at 20 °C to give a 70 : 30 mixture of 1,4,7- and 1,4,6-trisulfonic acids, which is used as mixed Dahl's acids.

1-Aminonaphthalene-4,7-disulfonic acid [*85-75-6*] (**106**) (4-aminonaphthalene-1,6-disulfonic acid), Dahl's acid III, $C_{10}H_9NO_6S_2$, M_r 303.3, and its sodium salt are readily soluble in water, but the calcium and barium salts are only sparingly soluble. Conversion to 1-hydroxynaphthalene-4,7-disulfonic acid is achieved by reverse-Bucherer reaction or diazotization and hydrolysis. Sulfonation (35 % oleum, 90 °C) yields 1-aminonaphthalene-2,4,7-trisulfonic acid.

Production. Although separation of **106** from the mixture obtained by sulfonation of naphthionic acid (see above) is not practicable on a large scale, the 1,4,7-isomer can be obtained directly in high yield by sulfonation of 1-aminonaphthalene-7-sulfonic acid with oleum.

1-Aminonaphthalene-4,8-disulfonic acid [*117-55-5*] (**117**) (4-aminonaphthalene-1,5-disulfonic acid), $C_{10}H_9NO_6S_2$, M_r 303.3, and its acid monosodium salt are sparingly soluble in cold water, but the disodium salt is readily soluble. Hydrolysis with sodium hydroxide at 200 °C yields 1-amino-8-hydroxynaphthalene-4-sulfonic acid; at higher temperature, 1,8-dihydroxynaphthalene-4-sulfonic acid is formed. Heating with bisulfite produces 1-hydroxynaphthalene-4,8-disulfonic acid. Diazo compounds couple with 1-aminonaphthalene-4,8-disulfonic acid to form azo compounds, in contrast to 2-aminonaphthalene-4,8-disulfonic acid, which reacts to form diazoamino compounds.

Production. Naphthalene is sulfonated under conditions that give predominantly the 1,5-disulfonic acid, and the sulfonation mass is nitrated at 20 °C [7]. 3-Nitronaphthalene-1,5-disulfonic acid is precipitated from the quenched reaction mixture as its iron(II) salt and removed. After dilution and liming out, the remainder of the mixed nitro solution is reduced with iron and dilute acid, and the 1,4,8-isomer is salted out preferentially in ca. 40 % yield. A small proportion (ca. 10 % of 1-aminonaphthalene-3,8-disulfonic acid) is then salted out, after which the more soluble 1-aminonaphthalene-5,7-disulfonic acid crystallizes on concentration.

1-Aminonaphthalene-5,7-disulfonic acid [*13306-42-8*] (**130**) (5-aminonaphthalene-1,3-disulfonic acid), $C_{10}H_9NO_6S_2$, M_r 303.3, and its sodium salt are very soluble in water. Caustic fusion produces 1-amino-5-hydroxynaphthalene-7-sulfonic acid, and sulfonation (40 % oleum, 130 °C) yields 1-aminonaphthalene-2,5,7-trisulfonic acid.

Production. 1-Aminonaphthalene-5-sulfonic acid (Section 6.2) in sulfuric acid solution is treated with 65 % oleum, and the mixture is heated at 120 °C for 4 h. The sulfonation mass, which contains mainly the 2,5,7-trisulfonic acid, is diluted with water, and the batch is heated at 130 °C for 10 h to cause desulfonation. The product crystallizes on cooling and, after isolation, is deacidified by treatment of the solution with lime. The final sodium salt solution is used directly for production of 1-amino-5-hydroxynaphthalene-7-sulfonic acid.

6.5. 2-Aminonaphthalenedisulfonic Acids

Although preparation of ten of the possible isomers has been reported [5], only processes for those five isomers that have been used as intermediates or dye components are described here.

2-Aminonaphthalene-1,5-disulfonic acid [*117-62-4*] (**126**), 5-sulfo-Tobias acid, $C_{10}H_9NO_6S_2$, M_r 303.32, is purified by crystallization of the dipotassium salt from water. Alkali fusion results in formation of 2-amino-5-hydroxynaphthalene-1-sulfonic acid. Sulfonation (40 % oleum, 100 °C) gives 2-aminonaphthalene-1,5,7-trisulfonic acid. Heating with aqueous sulfuric acid produces 2-aminonaphthalene-5-sulfonic acid. The diazo compound is

converted to 2-diazo-1-hydroxynaphthalene-5-sulfonic acid on treatment with alkaline hypochlorite.

Production. Sulfonation of Tobias acid to produce 2-aminonaphthalene-5-sulfonic acid (Section 6.3) proceeds via **126**, which is isolated from the quenched reaction mixture with careful avoidance of desulfonation.

Uses. As a diazo component in orange and red azo reactive dyes, **126** gives more bathochromic shades than Tobias acid.

2-Aminonaphthalene-3,6-disulfonic acid [*92-28-4*] (**123**) (3-aminonaphthalene-2,7-disulfonic acid), amino R acid, $C_{10}H_9NO_6S_2$, M_r 303.3.

Production. The sodium salt of 2-hydroxynaphthalene-3,6-disulfonic acid (Section 4.5) is aminated by heating with ammonia and ammonium bisulfite for 24 h at 160 °C. The charge is added to excess lime and heated to remove excess ammonia, and calcium sulfite is filtered off. The product is precipitated by acidification of the filtrate and purified by redissolving the paste in alkali and reprecipitating with acid. The yield is 90 %.

Uses. Amino R acid is used mainly as an intermediate for conversion to 2-amino-3-hydroxynaphthalene-6-sulfonic acid by caustic fusion at 250 °C.

2-Aminonaphthalene-4,8-disulfonic acid [*131-27-1*] (**118**) (3-aminonaphthalene-1,5-disulfonic acid), Cassella acid, C acid, $C_{10}H_9NO_6S_2$, M_r 303.32, and its salts are readily soluble in water.

Reduction with sodium amalgam desulfonates **118** to give 2-aminonaphthalene-8-sulfonic acid, whereas boiling with dilute sulfuric acid results in desulfonation and hydrolysis to give 2-hydroxynaphthalene-4-sulfonic acid. Alkali fusion (KOH, 215 °C) produces 2-amino-4-hydroxynaphthalene-8-sulfonic acid.

Production. The iron(II) salt of 3-nitronaphthalene-1,5-disulfonic acid (nitro-Armstrong acid) (Section 6.4) is reduced with iron in dilute acid [7].

A claimed improvement involves isolation of nitro-Armstrong acid from the nitration products of naphthalene-1,5-disulfonic acid as the crystalline magnesium salt prior to catalytic reduction to C acid [49].

Uses. Cassella acid is an important diazo component for yellow direct and reactive dyes.

2-Aminonaphthalene-5,7-disulfonic acid [*118-33-2*] (**129**) (6-aminonaphthalene-1,3-disulfonic acid), amino J acid, $C_{10}H_9NO_6S_2$, M_r 303.32, and the bis-alkali-metal salts are very soluble in water, but the mono-alkali-metal salts, especially the acid potassium salt, are sparingly soluble in cold water. Reduction with sodium amalgam produces 2-aminonaphthalene-7-sulfonic acid, and heating with ammonium bisulfite gives 2-hydroxynaphthalene-5,7-disulfonic acid.

Production. 2-Aminonaphthalene-1-sulfonic acid is sulfonated by heating with excess oleum for 12 h at 100 °C. This produces 2-aminonaphthalene-1,5,7-trisulfonic acid (**128**), which is desulfonated by heating the quenched acid mixture at 105 °C for 3 h. The product is filtered off after cooling and dissolved in hot aqueous alkali, and excess sulfate is removed by precipitation with lime. The resulting sodium salt liquor (80 % yield) is used directly for caustic fusion to give J acid, the major outlet.

2-Aminonaphthalene-6,8-disulfonic acid [*86-65-7*] (**124**) (7-aminonaphthalene-1,3-disulfonic acid), amino G acid, $C_{10}H_9NO_6S_2$, M_r 303.3, and its bis-alkali-metal salts are very soluble in water, but the acid salts, especially the acid potassium salt, are much less soluble.

Production. The disodium or dipotassium salt of 2-hydroxynaphthalene-6,8-disulfonic acid (Section 4.5) is heated with excess aqueous ammonia and ammonium bisulfite at 185 °C for 18 h. The reaction mixture is basified, heated to remove excess ammonia, neutralized, and evaporated while any residual sulfite is removed. The resulting amino G acid liquor (95 % yield) is used directly for caustic fusion to give γ acid, the major outlet.

6.6. Aminonaphthalenetrisulfonic Acids

Only those isomers that have been used as intermediates or dye components are described here. Many other isomers have been reported, as have aminonaphthalenetetrasulfonic acids [5], but they are of only academic interest. The major outlet for aminonaphthalenetrisulfonic acids

is in caustic fusion reactions to produce important aminohydroxynaphthalenedisulfonic acids.

142

143

144

1-Aminonaphthalene-2,4,8-trisulfonic acid [*76530-15-9*] (4-aminonaphthalene-1,3,5-trisulfonic acid), $C_{10}H_9NO_9S_3$, M_r 383.36, is not isolable as the free acid and always reverts to the sultam (**142**) with elimination of water between the peri-substituents. The trisodium salt is also water soluble but can be crystallized in the form of yellow plates. Desulfonation occurs with 20 % hydrochloric acid at 150 °C to form 1-aminonaphthalene-8-sulfonic acid and with 40 % sulfuric acid at 110 °C to give 1-aminonaphthalene-2,8-disulfonic acid.

Production. A sulfuric acid solution of 1-aminonaphthalene-8-sulfonic acid (Section 6.2) is treated with 65 % oleum in the presence of anhydrous sodium sulfate as a moderator, and the temperature is slowly increased to 85 °C. The quenched solution is neutralized with chalk, calcium sulfate is removed, and the calcium salt solution is basified with sodium carbonate. After removal of calcium carbonate, the resulting solution of the disodium salt is evaporated for subsequent caustic fusion to produce Chicago acid.

1-Aminonaphthalene-3,6,8-trisulfonic acid [*117-42-0*] (**143**) (8-aminonaphthalene-1,3,6-trisulfonic acid), Koch acid, T acid, $C_{10}H_9NO_9S_3$, M_r 383.36, and its alkali-metal salts are readily soluble in water. The solutions are unusual for this class of compound in that they exhibit no fluorescence. Hydrolysis with dilute sulfuric acid produces 1-hydroxynaphthalene-3,6,8-trisulfonic acid (Section 4.6), whereas diazotization followed by acid hydrolysis results in formation of the corresponding sultone. Reduction with zinc and alkali desulfonates **143** to give 1-amino-naphthalene-3,6-disulfonic acid. Amination gives 1,3-diaminonaphthalene-6,8-disulfonic acid.

Production. Naphthalene in sulfuric acid solution is treated with gradual addition of 65 % oleum and temperature profiling (to 160 °C) to optimize formation of the 1,3,6-trisulfonic acid. A mixture of sulfuric acid and nitric acids is added slowly at 40 °C to form 1-nitronaphthalene-3,6,8-trisulfonic acid (nitro-Koch acid) which is converted to neutral liquor by liming out. The liquor is reduced with iron powder in the presence of acetic acid and, after removal of iron residues, the crude product is isolated, as the acid calcium – sodium salt. This is purified by dissolution with sodium carbonate and removal of calcium carbonate. The trisodium salt liquor is concentrated before direct use in H acid manufacture. To obtain pure Koch acid, the 1-nitro-3,6,8-trisulfonic acid can be isolated before reduction. The reduction step can alternatively be carried out by hydrogenation of the aqueous solution of nitro-Koch acid in the presence of a nickel catalyst [50].

Uses. Apart from caustic fusion to give H acid, the other main use is the production of chromotropic acid (**66**) by treatment with strong caustic under pressure.

1-Aminonaphthalene-4,6,8-trisulfonic acid [*17894-99-4*] (**144**) (8-aminonaphthalene-1,3,5-trisulfonic acid), B acid, $C_{10}H_9NO_9S_3$, M_r 383.36, is reduced with zinc and alkali to 1-aminonaphthalene-4,6-disulfonic acid. Heating with aqueous sulfuric acid causes desulfonation to form 1-aminonaphthalene-6,8-disulfonic acid. Sulfonation (25 % oleum, 90 °C) gives the sultam of 1-aminonaphthalene-2,4,6,8-tetrasulfonic acid.

Production. Naphthalene is sulfonated under conditions that maximize formation of the 1,3,5-trisulfonic acid (Section 2.4), followed by nitration with H_2SO_4–HNO_3 in situ at 35 °C. After quenching, neutralization with calcium carbonate, and reduction of the nitro-derivative with iron under acid conditions, the byproduct 1-aminonaphthalene-3,6,8-trisulfonic acid (18 % yield) is selectively precipitated by acidification. The desired isomer is then precipitated by further acidification and salting of the filtrates, and

finally purified by reprecipitation. Overall yield is 25 – 30 %.

Uses. Alkali fusion of B acid yields K acid. A special outlet for purified B acid is in the synthesis of the drug suramin sodium (Bayer 205) (**145**). 1-Aminonaphthalene-4,6,8-trisulfonic acid is acylated with 2-nitrotoluyl chloride, and this product is reduced and acylated with *m*-nitrobenzoyl chloride. This intermediate is reduced and finally phosgenated to give **145**, which has been used to treat trypanosomiasis and onchocerciasis.

145

2-Aminonaphthalene-1,5,7-trisulfonic acid [*55524-84-0*] (**128**) (6-aminonaphthalene-1,3,5-trisulfonic acid), $C_{10}H_9NO_9S_3$, M_r 383.36, and its salts are readily soluble in water. Alkali fusion (65 % NaOH, 220 °C) forms 2-amino-5-hydroxynaphthalene-1,7-disulfonic acid. Desulfonation to give 2-aminonaphthalene-5,7-disulfonic acid occurs on heating with dilute sulfuric acid. Diazotization and treatment with sodium carbonate yield the diazo oxide of 2-diazo-1-hydroxynaphthalene-5,7-disulfonic acid.

Production. Vigorous sulfonation of Tobias acid to produce 2-aminonaphthalene-5,7-disulfonic acid is described in Section 6.5. The intermediate **128** is obtained by quenching the sulfonation mass and liming out carefully to avoid desulfonation. The calcium salt solution is converted to the sodium salt with sodium carbonate and used as a total liquor for conversion to 2-amino-5-hydroxynaphthalene-1,7-disulfonic acid.

2-Aminonaphthalene-3,6,8-trisulfonic acid [*118-03-6*] (**146**) (7-aminonaphthalene-1,3,6-trisulfonic acid), $C_{10}H_9NO_9S_3$, M_r 383.36, and its disodium salts are soluble in water, but the dipotassium salt is much less soluble. Reduction with zinc dust and alkali results in 2-aminonaphthalene-3,6-disulfonic acid, and caustic fusion at 240 °C gives 2-amino-8-hydroxynaphthalene-3,6-disulfonic acid.

Production. 2-Aminonaphthalene-6,8-disulfonic acid (Section 6.5) is sulfonated with 65 % oleum at 125 °C for 12 h in the presence of anhydrous sodium sulfate. After quenching and liming out, the hot solution of calcium salt is basified with sodium carbonate and the resulting solution of the trisodium salt is used directly for caustic fusion to give 2-amino-8-hydroxynaphthalene-3,6-disulfonic acid.

146

6.7. Diaminonaphthalenesulfonic Acids

4,5-Diaminonaphthalene-1-sulfonic acid [*6362-18-1*] (**147**) 1,8-diaminonaphthalene-4-sulfonic acid, $C_{10}H_{10}N_2O_3S$, M_r 238.27.

Production. 1-Nitronaphthalene (Section 5.1) is sulfonated with oleum at 20 °C, and the sulfonation mass is nitrated at 35 °C [7]. After quenching and liming out, the liquors are reduced with iron powder under slightly acidic conditions. After removal of iron residues, the product **147** is isolated in 40 % yield by acidifying and salting.

Uses. 4,5-Diaminonaphthalene-1-sulfonic acid is used as an intermediate for 4,5-dihydroxynaphthalene-1-sulfonic acid (Section 4.7) and perimidine derivatives.

147

148

149

150

5,6-Diaminonaphthalene-1-sulfonic acid [*84-92-4*] (**148**) 1,2-diaminonaphthalene-5-sulfonic acid, $C_{10}H_{10}N_2O_3S$, M_r 238.27.

Production. 1-Aminonaphthalene-5-sulfonic acid (Section 6.2) is coupled with diazotized aniline, and the resulting isolated azo compound (purpurin base) is reduced by heating with zinc and ammonia at 100 °C and allowing ammonia and aniline to distill off [7]. The product (**148**) is isolated in 76 % yield by acidification of the screened liquors.

Uses. 5,6-Diaminonaphthalene-1-sulfonic acid is used as an intermediate for naphthotriazoles. A green pigment (C.I. Pigment Green 9) is obtained by treatment with iron(III) salts.

6,8-Diaminonaphthalene-1-sulfonic acid (**149**) 1,3-diaminonaphthalene-8-sulfonic acid, M_r 238.27, is prepared by amination of 1-aminonaphthalene-3,8-disulfonic acid (Section 6.4) or 1-hydroxynaphthalene-3,8-disulfonic acid but has no significant use.

6,8-Dianilinonaphthalene-1-sulfonic acid [*129-93-1*] (**140**), diphenyl epsilon acid, $C_{22}H_{18}N_2O_3S$, M_r 390.38.

Production. 1-Aminonaphthalene-3,8-disulfonic acid (Section 6.4) is heated with excess aniline in the presence of aniline sulfate at 130 °C.

Uses. A dye component as exemplified in **141**.

1,4-Diaminonaphthalene-2-sulfonic acid [*6357-89-7*] (**150**), $C_{10}H_{10}N_2O_3S$, M_r 238.27.

Production. 1-Aminonaphthalene-2-sulfonic acid (Section 6.2) is coupled with diazotized aniline, and the resulting azo compound is reduced in a process analogous to that used for **148**.

6.8. Diaminonaphthalenedisulfonic Acids

3,8-Diaminonaphthalene-1,5-disulfonic acid [*19659-81-5*] (**151**), amino Cacid, $C_{10}H_{10}N_2O_6S_2$, M_r 318.32.

Production. Naphthalene-1,5-disulfonic acid sulfonation mass is nitrated to give the 3,8-dinitro derivative [7]. The quenched and limed-out liquor is reduced with iron to give **151**.

4,8-Diaminonaphthalene-2,6-disulfonic acid [*6362-06-7*] (**152**), $C_{10}H_{10}N_2O_6S_2$, M_r 318.32.

Production. Naphthalene-2,6-disulfonic acid is dinitrated and reduced in a similar way to the 1,5-isomer [7].

4,5-Diaminonaphthalene-2,7-sulfonic acid [*6362-11-4*] (**153**), Alen acid, $C_{10}H_{10}N_2O_6S_2$, M_r 318.32.

Production. Naphthalene-2,7-disulfonic acid is dinitrated and reduced in a similar way to the 1,5-isomer [7].

151

152

153

6.9. Toxicity

Aminonaphthalenesulfonic acids were once regarded as innocuous compared to the parent amines. Later, however, some risk was recognized to be involved [9]. Although several aminonaphthalene mono- and disulfonic acids are listed in the EPA inventory [14] as having mildly toxic and irritant properties, no evidence of carcinogenic properties exists.

The hypothesis that water-soluble agents are less likely to be absorbed by bodily organs is supported by the full and rapid excretion of ^{35}S-labeled Tobias acid in experiments with rats [51]. Neither 2-naphthylamine nor its derivatives were detected in these experiments, indicating that, given the short dwell time of water-soluble compounds in the body, desulfonation is unlikely.

7. Aminonaphthols

Although all 14 isomeric aminonaphthols have been described [5], they are less useful than their sulfonic acids (Chap. 8) and only those of commercial significance will be identified. As a class they are amphoteric and dissolve in both acid and alkali. One reason for their lack of use is that their alkaline solutions are very readily oxidized.

There are four main methods of preparation:

1) Caustic fusion of aminonaphthalenesulfonic acids as previously mentioned under properties of 1-aminonaphthalene-5-sulfonic acid, 1-aminonaphthalene-6-sulfonic acid, 1-aminonaphthalene-7-sulfonic acid, and 1-aminonaphthalene-8-sulfonic acid (Section 6.2), as well as 2-aminonaphthalene-5-sulfonic acid, 2-aminonaphthalene-7-sulfonic acid, and 2-aminonaphthalene-8-sulfonic acid (Section 6.3). With some isomers (e.g., 1,4- and 2,6-), hydroxynaphthalenesulfonic acids are formed by replacement of the amino group rather than the sulfonic acid group.
2) Bucherer amination of dihydroxynaphthalenes with ammonia and bisulfite. Alternatively, the reverse-Bucherer reaction can be applied to certain naphthalenediamines.
3) Desulfonation of certain aminohydroxynaphthalenesulfonic acids by heating with dilute acid or by treatment with sodium amalgam.
4) Reduction of arylazo, nitroso, or nitro derivatives of 1-naphthol or 2-naphthol by zinc or sodium. A more recent process uses aqueous hydrazine as the reducing agent [52].

4-Amino-1-naphthol [*2834-90-4*] (**154**), 4-hydroxy-1-aminonaphthalene, 4-amino-1-naphthalenol, $C_{10}H_9NO$, M_r 159.2.

Production. Orange I (**25**) in aqueous alkaline solution is treated with sodium dithionite at 40 – 50 °C, and the resulting suspension is heated to 70 °C to complete the reaction. The crude product is collected by filtration and dissolved in hot aqueous hydrochloric acid in the presence of a reducing agent. On cooling, needles of the hydrochloride salt crystallize and can be isolated in 70 % yield. Alternatively, the crude paste may be dissolved in dilute alkali in the presence of a reducing agent and acylated with acetic anhydride or acryloyl chloride, for example, to give 4-acetylamino-1-naphthol or 4-acryloylamino-1-naphthol, which have been used as azo coupling components.

Uses. 4-Amino-1-naphthol is used as a polymerization inhibitor.

5-Amino-1-naphthol [*83-55-6*] (**155**), 5-hydroxy-1-aminonaphthalene, 5-amino-1-naphthalenol, Purpurol, $C_{10}H_9NO$, M_r 159.2.

Production. 1-Aminonaphthalene-5-sulfonic acid paste (Section 6.2) is added to molten sodium hydroxide at 200 °C, and the reaction is completed by heating slowly to 250 °C and maintaining this temperature for 3 h [7]. After dilution and careful neutralization with hydrochloric acid, 5-amino-1-naphthol precipitates in 85 % yield (*mp* 192 °C).

Uses. 5-Amino-1-naphthol is used as a coupling component for azo dyes (coupling takes place ortho to the amino or hydroxyl group, or para to the hydroxyl group depending on the pH), and as an intermediate for sulfur dyes.

7-Amino-1-naphthol [*4384-92-3*] (**156**), 8-hydroxy-2-aminonaphthalene, 7-amino-1-naphthalenol, $C_{10}H_9NO$, M_r 159.2.

Production. 2-Aminonaphthalene-8-sulfonic acid (Section 6.3) is heated with molten potassium hydroxide for 2 – 3 h at 260 °C in an autoclave. The product is obtained in 74 % yield after dilution and acidification of the melt.

1-Amino-1-naphthol [*2834-92-6*] (**157**), 1-amino-2-naphthalenol, is prepared by reduction of Orange II (1-*p*-sulfobenzeneazo-2-naphthol) by a process analogous to that described for 4-amino-1-naphthol, but it has no significant use.

1-Amino-2-ethoxynaphthalene [*118-30-9*] (**158**), $C_{12}H_{13}NO$, M_r 188.

Production. A solution of 2-ethoxynaphthalene (Section 3.2) in 1,2-dichlorobenzene is reacted with nitric acid at 45 °C. The organic layer is separated and washed at 60 °C before cooling to crystallize 1-nitro-2-ethoxynaphthalene (*mp* 95 – 100 °C) in 80 % yield. Reduction with iron gives **158** in 74 % yield.

Uses. Sulfonation (H_2SO_4, 60 °C) of **158** gives 1-amino-2-ethoxynaphthalene-6-sulfonic acid for use principally as an intermediate component in azo direct green dyes.

8-Amino-2-naphthol [*118-46-7*] (**159**), 1-amino-7-naphthol, 8-amino-2-naphthalenol, Cyanol, $C_{10}H_9NO$, M_r 159.2.

Production. The sodium salt of 1-aminonaphthalene-7-sulfonic acid (Section 6.2) is added to 80 % potassium hydroxide at 210 °C, and the reaction is completed by heating for 6 h at 230 °C [7]. After dilution and careful acidification with hydrochloric acid, the acid solution is screened to remove impurities and neutralized to precipitate **159** in 80 % yield (*mp* 207 °C).

Uses. Sulfonation gives 1-amino-7-hydroxynaphthalene-4-sulfonic acid. The *N*-acetyl derivative is an important coupling component for after-chrome and metal-complex dyes, e.g., C.I. Mordant Black 38 and C.I. Acid Black 60.

8. Aminohydroxynaphthalenesulfonic Acids

Many of the letter acids listed in Table 1 are aminohydroxynaphthalenesulfonic acids, (aminonaphtholsulfonic acids), the most important of which are probably the H, J, and γ acids [17]. Most of the large-scale use of this class involves the production of water-soluble azo dyes. Only those products of known use are dealt with on an individual basis. Registration of compounds in the European core inventory (ECOIN) in 1981 has been used as a guide to commercial applications. Thirteen aminonaphthol monosulfonic acids and seven aminonaphthol disulfonic acids are listed therein.

Nomenclature is used as in Table 1, based on tradition (and current common usage) with precedence given to the amino and then the hydroxyl group. The IUPAC convention, based on derivatives of naphthalenesulfonic acids, is added in parentheses for completion.

A number of aminohydroxynaphthalenetrisulfonic acids and diaminohydroxynaphthalenesulfonic acids have been prepared [5] by routes analogous to these described here but they have no technical advantage over the simpler derivatives.

8.1. Production and Properties

Four main routes are available depending on the substitution pattern required (route 1 predominates as the basis for all major aminonaphthol sulfonic acids).

1) Caustic fusion hydrolysis of aminonaphthalenedi- and trisulfonic acids.
   One sulfonic acid group of aminonaphthalenedi- and trisulfonic acids (see Chap. 6) can be hydrolyzed in a way similar to the selective hydrolysis described for naphthalenedi- and trisulfonic acids (Chap. 4).
   The following ten derivatives (**160–169**) manufactured by this route are all commercially important and are described individually later. With α, β-disulfonic acids, the α-group is the more mobile; with α, α-configurations, reaction occurs with the sulfonic acid group in the ring not containing the amino group. Hydrolysis of a sulfonic acid group in the peri-position to the amino group is particularly facile.

160

161

162

163

164

165

166

167

168

169

2) Reduction of nitroso or arylazo derivatives of hydroxynaphthalenesulfonic acids.
   Hydroxynaphthalenesulfonic acids react readily with nitrous acid or diazo compounds with the introduction of substituents ortho to the hydroxyl group. Reduction of the nitroso or azo substituent leads to an ortho arrangement of the amino and hydroxyl groups that is difficult to achieve by other routes.
   The nitrosation route can be extended to include 1-naphthol or 2-naphthol, because simultaneous reduction and sulfonation can be achieved to obtain, for example, 1-amino-2-hydroxynaphthalene-4-sulfonic acid (**170**) directly from 2-naphthol.
3) Sulfonation of aminonaphthols.
   When an aminonaphthol is readily accessible (Chap. 7), sulfonation may lead to useful aminohydroxynaphthalenesulfonic acids that are not otherwise readily obtainable. However, isomer formation and the need for separation may be a problem.
4) Selective desulfonation of aminohydroxynaphthalenedisulfonic acids.
   Facile removal of certain α-sulfonic acid groups may occasionally make an aminohydroxynaphthalenedisulfonic acid (e.g., K acid) a viable starting material.

Aminohydroxynaphthalenesulfonic acids resemble aminonaphthalenesulfonic acids in forming internal salts. The monosulfonic acids are therefore sparingly soluble in water and are isolated as the free acid. The disulfonic acids are much more soluble in water and are often isolated as the monosodium or monopotassium salts even under acidic conditions.

Coupling with diazo compounds is the most important property of aminohydroxynaphthalenesulfonic acids, and many of them couple under both acidic and alkaline conditions. The hues and properties of the resulting *o*-aminoazo or *o*-hydroxyazo dyes vary widely. The most useful products are derived from alkaline-coupled J acid (monoazo oranges) or H acid (monoazo reds), acid-coupled γ acid (monoazo reds), and acid- and alkali-twice-coupled H acid (disazo blues and blacks), even though all of these letter acids undergo both acid and alkaline coupling.

Although all aminohydroxynaphthalenesulfonic acids are diazotizable, only 1-amino-2-hydroxynaphthalene-4-sulfonic acid and its derivatives are industrially important as diazo components.

8.2. Aminohydroxynaphthalene-monosulfonic Acids

1-Amino-2-hydroxynaphthalene-4-sulfonic acid [*116-63-2*] (**170**) (4-amino-3-hydroxynaphthalene-1-sulfonic acid), Böniger acid, $C_{10}H_9NO_4S$, M_r 239.2, is obtained as white or gray needles of the hemihydrate, which is only sparingly soluble in hot water. The alkali-metal salts are soluble in water, but the solutions slowly oxidize in air. Oxidation with nitric acid gives 1,2-naphthoquinone-4-sulfonic acid.

Production. 2-Naphthol is dissolved in dilute aqueous sodium hydroxide and precipitated in finely divided form by addition of sulfuric acid at 5 °C [7]. Sodium nitrite solution is added to the slightly alkaline suspension, followed by sulfuric acid to effect the nitrosation while the temperature is held at 5 – 8 °C. The suspension of 1-nitroso-2-naphthol is neutralized with aqueous sodium hydroxide; a solution of sodium bisulfite is then added. The temperature is allowed to rise to 20 °C, and the soluble bisulfite addition complex (**171**) is formed. Excess sulfuric acid is then added and the temperature is raised to 40 °C, whereupon reductive rearrangement takes place and the product slowly crystallizes at 50 °C. Filtration and washing give the product as a 25 % paste in 80 % yield. All plant items and reactants must be free from iron to avoid complex formation.

Uses. The 1,2,4-acid paste is usually converted directly to the diazo oxide (**172**) by addition to excess sodium nitrite solution in the presence of copper(II) sulfate and in the absence of mineral acid [7]. After completion of the reaction, the product is precipitated by careful addition of excess sulfuric acid and isolated in 95 % yield as an orange-gray sandy paste. This can be dried if required for further nonaqueous processing at a temperature not exceeding 50 °C to avoid decomposition.

The so-called diazo-1,2,4-acid (**172**) is usually thought to exist as the naphthoquinone – diazide (**173**; 4-diazo-3,4-dihydro-3-oxonaphthalene-1-sulfonic acid) [26]. It is an important component in azo dyes for after-chroming, e.g., C.I. Mordant Black 3 (**27**), C.I. Mordant Black 17, and C.I. Mordant Red 7 (**174**), and for producing preformed chromium complex dyes such as C.I. Acid Violet 90 (the 2 : 1 chromium complex of **174**).

170

171

172 **173**

174 **175**

176

The quinone – diazide **173** [*4857-47-0*], is remarkably stable, which allows direct nitration in sulfuric acid solution by treatment with mixed acid over 8 h at 10 – 15 °C to give the so-called 6-nitrodiazo-1,2,4-acid [*5366-84-7*] (**175**) as a paste in 85 % yield after isolation and slurry washing. This nitroderivative is also considered to exist in the stable quinone – diazide form (4-diazo-3,4-dihydro-7-nitro-3-oxonaphthalene-1-sulfonic acid) and is an even more important component for metallized and metallizable dyes than is **173**; typical examples are C.I. Acid Black 52 (chromium complex of **176**), C.I. Direct Red 173, C.I. Reactive Black 1, C.I. Mordant Black 1 (**176**), and C.I. Mordant Black 11.

Chlorination of dry **173** in chlorosulfonic acid solution under a positive pressure of chlorine results in formation (50 % yield) of the diazo oxide of 6-chloro-1-amino-2-hydroxynaphthalene-4-sulfonic acid, which is, however, of lesser importance as a diazo component.

1-Amino-2-hydroxynaphthalene-6-sulfonic acid [*5639-34-9*] (**177**) (5-amino-6-hydroxynaphthalene-2-sulfonic acid), amino-Schaeffer acid, $C_{10}H_9NO_4S$, M_r 239.2, is obtained as needles or prisms that are only slightly soluble in boiling water. The sodium salt is soluble in water but can be isolated as the hemipentahydrate. Diazotization does not occur in mineral acid medium. The diazo oxide is formed by reaction with sodium nitrite in the presence of copper(II) sulfate.

Production. 2-Hydroxynaphthalene-6-sulfonic acid is nitrosated in aqueous solution, and the resulting nitroso derivative is reduced in situ by addition of zinc dust to the acidified batch, with the temperature allowed to rise to 40 °C [7]. The precipitated product is isolated in 70 % yield.

177

Uses. The sodium salt of **177** has found some use in the detection of potassium and as a photographic developer (Eikonogen). The *O*-ethyl derivative of **177** is an important middle component for dis- and trisazo green dyes.

1-Amino-2-ethoxynaphthalene-6-sulfonic acid [*118-28-5*] (**178**) can be obtained by ethylation of **177** with diethyl sulfate in methanol [53] or by sulfonation of 1-amino-2-ethoxynaphthalene (**158**; Chap. 7). The older, established route is based on Schaeffer acid and a three-step process involving ethylation, nitration, and reduction.

Important products derived from **178** are C.I. Direct Greens 23, 33 (**179**), 34, and 38.

1-Amino-5-hydroxynaphthalene-6-sulfonic acid [*58596-07-9*] (**180**) (5-amino-1-hydroxynaphthalene-2-sulfonic acid), $C_{10}H_9NO_4S$, M_r 239.2.

Production. 5-amino-1-naphthol (Chap. 7) is sulfonated with 96 % sulfuric acid at 20 °C, and the sparingly soluble product is isolated after quenching.

1-Amino-5-hydroxynaphthalene-7-sulfonic acid [*489-78-1*] (**160**) (8-amino-4-hydroxynaphthalene-2-sulfonic acid), M acid, $C_{10}H_9NO_4S$, M_r 239.2, and its sodium salt are sparingly soluble in water. Coupling with diazo compounds takes place under acidic and alkaline conditions, but a bisazo derivative cannot be obtained. Reaction with bisulfite gives 4,8-dihydroxynaphthalene-2-sulfonic acid.

Production. 1-Aminonaphthalene-5,7-disulfonic acid (Section 6.4) is heated with concentrated sodium hydroxide for 16 h at 172 – 176 °C. After the reaction mixture is quenched, acidified, and purged of sulfur dioxide, the product is isolated in 80 % yield.

1-Amino-8-hydroxynaphthalene-4-sulfonic acid [*83-64-7*] (**161**) (4-amino-5-hydroxynaphthalene-1-sulfonic acid), S acid, $C_{10}H_9NO_4S$, M_r 239.2, is only sparingly soluble in hot water. Reaction with bisulfite gives 4,5-dihydroxynaphthalene-1-sulfonic acid. Diazo compounds couple under acid conditions α to the amino group and under alkaline conditions α to the hydroxy group; bisazo derivatives can be obtained.

Production. 1-Aminonaphthalene-4,8-disulfonic acid (Section 6.4) is heated with concentrated potassium hydroxide at 200 – 230 °C.

Uses. The S acid and its acetyl derivative are used as azo coupling components in e.g., C.I. Mordant Green 14, C.I. Mordant Blue 7, and C.I. Direct Green 39.

1-Amino-8-hydroxynaphthalene-6-sulfonic acid [*35400-55-6*] (**181**) (5-amino-4-hydroxynaphthalene-2-sulfonic acid), $C_{10}H_9NO_4S$, M_r 239.2.

Production. 1-Aminonaphthalene-6,8-disulfonic acid gives **181** on fusion with 50 % potassium hydroxide at 200 °C, but because the former is not readily available, a more convenient process is the desulfonation of K acid (**167**) by boiling with zinc dust in aqueous sodium hydroxide solution.

2-Amino-1-hydroxynaphthalene-4-sulfonic acid [*567-13-5*] (**182**) (3-amino-4-hydroxynaphthalene-1-sulfonic acid), $C_{10}H_9NO_4S$, M_r 239.2.

Production. Although **182** may be obtained from 2-nitroso-1-naphthol by heating with bisul-

fite, this is less efficient than the corresponding reaction with 1-nitroso-2-naphthol. The preferred method is reduction of the azo dye derived from aniline and 1-hydroxynaphthalene-4-sulfonic acid with sodium dithionite or hydrazine [52].

Uses. 2-Amino-1-hydroxynaphthalene-4-sulfonic acid forms the stable quinone – diazide, 3-diazo-3,4-dihydro-4-oxonaphthalene-1-sulfonic acid [*20680-48-2*] (**183**) when diazotized in the presence of copper(II) sulfate. The stability of **183** and **173**, together with their moderate photosensitivity, led to their use in the earliest diazotype reprographic processes.

2-Amino-3-hydroxynaphthalene-6-sulfonic acid [*6399-72-0*] (**162**) (6-amino-7-hydroxynaphthalene-2-sulfonic acid), RM acid, $C_{10}H_9NO_4S$, M_r 239.2, is only sparingly soluble in hot water.

Production. 2-Aminonaphthalene-3,6-disulfonic acid (Section 6.5) is fused with 85 % potassium hydroxide at 180 °C for 20 h [7]. After quenching and acidification, the product is isolated in 75 % yield.

2-Amino-5-hydroxynaphthalene-7-sulfonic acid [*87-02-5*] (**163**) (7-amino-4-hydroxynaphthalene-2-sulfonic acid), J acid, $C_{10}H_9NO_4S$, M_r 239.2, is only slightly soluble (0.1 %) in cold water but readily soluble at 100 °C. The alkali-metal salts are readily soluble in water. Diazo compounds are normally coupled with J acid under alkaline conditions with reaction in the 6-position (ortho to hydroxyl); however, under acid conditions, coupling can occur in the 1-position. Reaction with bisulfite gives 4,7-dihydroxynaphthalene-2-sulfonic acid. The N-acylation, Nalkylation, and N-arylation reactions are important.

Production. A concentrated disodium salt solution of 2-aminonaphthalene-5,7-disulfonic acid (Section 6.5) is added to 72 % sodium hydroxide at 150 °C [7]. After heating to 187 °C over 10 h reaction is continued at this temperature for a further 8 h until completion of the reaction is indicated by giving equivalent diazotization and coupling titers for a worked-up sample. Quenching, acidification, purging of sulfur dioxide, and filtration at 55 °C followed by washing with water at 50 °C result in an 88 % yield of paste. Purification by salting out the sodium salt from a hot alkaline solution gives a 90 % recovery of the product as gray crystals.

An improved process with 90 % yield is claimed by feeding the concentrated 2-aminonaphthalene-5,7-disulfonic acid liquor and the caustic liquor simultaneously into the fusion reactor to maintain more stable conditions [54].

Uses. The J acid is an important coupling component in a wide range of direct dyes [e.g., C.I. Direct Blue 71 (**184**)] and reactive dyes [e.g., C.I. Reactive Orange 1 and C.I. Reactive Red 9 (**185**)].

184

185

Many J acid derivatives, e.g., *N*-acetyl, *N*-methyl, *N*-phenyl, di-J acid, and the urea carbonyl J acid, are of comparable importance to J acid itself.

7-Acetamido-4-hydroxynaphthalene-2-sulfonic acid [*6334-97-0*] (**186**), *N*-acetyl J acid, is produced by reaction of the sodium salt of J acid with acetic anhydride in aqueous solution at 20 – 30 °C, followed by heating at 95 °C with sodium carbonate to hydrolyze any *O*-acetyl derivative present (yield 85 %). It is used to produce C.I. Acid Orange 27, C.I. Acid Red 137, and C.I. Direct Red 77.

186

4-Hydroxy-7-methylaminonaphthalene-2-sulfonic acid [*22346-43-6*] (**187**), *N*-methyl J acid, is produced by reaction of 2,5-dihydroxynaphthalene-7-sulfonic acid (Section 4.7) with methylamine and aqueous sodium bisulfite at 96 °C for 36 h (yield 83 %). It is used to produce C.I. Reactive Orange 4, C.I. Reactive Orange 13, and C.I. Reactive Red 33.

187

4-Hydroxy-7-phenylaminonaphthalene-2-sulfonic acid [*119-40-4*] (**188**), *N*-phenyl J acid, is produced by reaction of J acid with aniline in aqueous sodium bisulfite at reflux for 40 h (yield 85 %). It is used to produce C.I. Direct Violet 7, C.I. Direct Violet 9, C.I. Direct Violet 51, C.I. Direct Blue 78, and C.I. Direct Blue 168.

188

7,7′-Iminobis(4-hydroxynaphthalene-2-sulfonic acid) [*87-03-6*] (**189**), J acid imide, di-J acid, is produced by heating the sodium salt of J acid in aqueous sodium bisulfite at 106 °C for 36 h (yield 89 %). It is used to produce C.I. Direct Reds 31 and 149, as well as C.I. Direct Violets 48, 66, and 102.

189

7,7′-Urylenebis(4-hydroxynaphthalene-2-sulfonic acid) [*134-47-4*] (**190**), J acid urea, carbonyl J acid, is produced by reacting the sodium salt of J acid with phosgene in aqueous solution at 30 °C and maintaining alkalinity with sodium carbonate. After being heated to 80 °C, the product is salted out with sodium chloride (yield ca. 100 %). It is used to produce C.I. Direct Orange 26; C.I. Direct Reds 4, 14, 23, and 80; and C.I. Direct Brown 112.

190

The related *N*-chloroacetyl, *N*-benzoyl, *N*-(4-aminobenzoyl), *N*-(3-aminobenzoyl), *N*-(3-methyl-4-aminobenzoyl), *N*-(4-methoxyphenyl), *N*-(3-carboxyphenyl), and *N*-(4-aminophenyl) derivatives are prepared by similar methods but have comparatively minor importance.

2-Amino-6-hydroxynaphthalene-8-sulfonic acid [*86-61-3*] (**191**), (7-amino-3-hydroxynaphthalene-1-sulfonic acid), $C_{10}H_9NO_4S$, M_r 239.2.

Production. 6-Nitrodiazo-1,2,4-acid (**175**) is heated with aqueous sodium sulfite solution in the presence of copper(II) sulfate. The solution is then acidified and heated further to cause desulfonation. The resulting nitrohydroxynaphthalenesulfonic acid is reduced with iron in the presence of acid [55].

This process is preferred to the traditional deamination of **175** with ethanol in the presence of a copper catalyst.

2-Amino-8-hydroxynaphthalene-6-sulfonic acid [*90-51-7*] (**164**) (6-amino-4-hydroxynaphthalene-2-sulfonic acid), γ acid, $C_{10}H_9NO_4S$, M_r 239.2, is obtained as white or gray crystals which are only sparingly soluble in water even at 100 °C (0.4 %). The sodium salt dissolves readily in water to form solutions that exhibit a blue fluorescence. Coupling with

diazo compounds is usually carried out under acid conditions and occurs in the 1-position; coupling in the 7-position can be effected in alkaline solution.

Production. 2-Aminonaphthalene-6,8-disulfonic acid liquor (Section 6.5) is added over 16 h to 70 % sodium hydroxide at 190 °C, while the water is allowed to evaporate to maintain the temperature [7]. The reaction mixture is then heated for a further 6 h. Completion of the reaction is indicated by a worked-up sample giving identical titers for both diazotization and coupling. The batch is diluted with water, acidified, and heated at 75 °C to expel sulfur dioxide. The product is filtered off at 55 °C and washed with warm water; yield is 84 %.

An improved process with 90 % yield is claimed by feeding concentrated 2-aminonaphthalene-6,8-disulfonic acid dipotassium salt liquor and caustic soda liquor simultaneously into the fusion reactor [54].

Uses. The so-called γ acid is an important component in azo dyes; coupling can be carried out under acid or alkaline conditions. The *o*-amino azo configuration obtained under acid conditions leads to high lightfastness of special importance in monoazo acid red dyes for wool and polyamide, such as C.I. Acid Reds 37, 57, and 266 (**192**). Disazo direct dyes are also obtained by acid coupling (e.g., C.I. Direct Red 75) but trisazo blacks, exemplified by C.I. Direct Black 80 (**193**), which use γ acid as an alkali-coupled end and middle component, are of more significance as replacements for benzidine-based black direct dyes.

192

193

As with J acid, the *N*-acetyl and *N*-methyl derivatives are also important.

6-Acetamido-4-hydroxynaphthalene-2-sulfonic acid [*6361-41-7*] (**194**), *N*-acetyl γ acid, is produced by reaction of the sodium salt of γ acid with acetic anhydride in aqueous solution at 20 – 30 °C (yield 87 %). It is used to produce C.I. Acid Red 68, C.I. Reactive Orange 7, and C.I. Reactive Orange 16.

194

4-Hydroxy-6-methylaminonaphthalene-2-sulfonic acid [*6259-53-6*] (**195**), *N*-methyl γ acid, is produced by reaction of 2,8-dihydroxynaphthalene-6-sulfonic acid (Section 4.7) with methylamine in aqueous sodium bisulfite at 96 °C for 36 h (yield 95 %). It is used to produce C.I. Acid Brown 91.

195

Other substituted γ acids that have been similarly used in specialized azo dyes include the *N*-β-hydroxymethyl, *N*-phenyl, *N*-(4-methoxyphenyl), *N*-(4-carboxyphenyl), *N*-(3-sulfophenyl), and *N*-(4-amino-3-sulfophenyl) derivatives.

2-Amino-8-hydroxynaphthalene-7-sulfonic acid (Na salt, [*74525-31-8*]) (**196**) (7-amino-1-hydroxynaphthalene-2-sulfonic acid), $C_{10}H_9NO_4S$, M_r 239.2.

Production. 7-Amino-1-naphthol (Chap. 7) is sulfonated at 0 °C with 96 % sulfuric acid

to yield 65 % of **196** together with 16 % of the isomeric 2-amino-8-hydroxynaphthalene-5-sulfonic acid [*21013-47-8*] (**197**). Separation by fractional precipitation of the sodium salt is not easy, but should the latter isomer be required the sulfonation temperature is increased to 30 °C, where-upon the product ratio changes from 65 : 16 to 50 : 35.

8.3. Aminohydroxynaphthalenedisulfonic Acids

1-Amino-2-hydroxynaphthalene-3,6-disulfonic acid [*2007-20-7*] (**198**) (4-amino-3-hydroxynaphthalene-2,7-disulfonic acid), $C_{10}H_9NO_7S_2$, M_r 319.3.

Production. R acid (Section 4.5) is coupled with diazotized aniline, and the isolated azo product is then reduced with sodium dithionite by a process similar to that employed for other *o*-aminonaphthols.

1-Amino-8-hydroxynaphthalene-2,4-disulfonic acid [*82-47-3*] (**165**) (4-amino-5-hydroxynaphthalene-1,3-disulfonic acid), Chicago acid, 2 S acid, $C_{10}H_9NO_7S_2$, M_r 319.3, and its acid sodium salt are readily soluble in water; the latter can be salted out with sodium chloride. In alkaline solution, coupling with diazo compounds takes place ortho to the hydroxyl group. Alkaline hydrolysis at 170 °C gives 1,8-dihydroxynaphthalene-2,4-disulfonic acid. Heating with dilute sulfuric acid results in desulfonation to give 1-amino-8-hydroxynaphthalene-2-sulfonic acid.

Production. A solution of the disodium salt of naphthosultam-2,4-disulfonic acid (**142**; Section 6.6) is concentrated and mixed with potassium hydroxide liquor at 130 °C [7]. The temperature is raised to 155 °C over 20 h to complete the reaction. After being cooled and diluted with water, the melt is run into excess hydrochloric acid and the monopotassium salt is collected by filtration at 30 °C and slurry washed with recycling of the wash liquors. A yield of 87 % is obtained.

Uses. Chicago acid is used as a coupling component for C.I. Direct Blue 1 (**199**), C.I. Direct Blue 22, and C.I. Direct Blue 76 (the dicopper complex of demethylated **199**).

1-Amino-8-hydroxynaphthalene-3,6-disulfonic acid [*90-20-0*] (**166**) (4-amino-5-hydroxynaphthalene-2,7-disulfonic acid), H acid, $C_{10}H_9NO_7S_2$, M_r 319.3, is usually isolated as its monosodium salt [*5460-09-3*], a gray powder that is slightly soluble in cold water and readily soluble in hot water; the disodium salt is very soluble in water. With diazo compounds, H acid couples ortho to the amino group under acid conditions and ortho to the hydroxyl group under alkaline conditions. Bisazo derivatives are formed by stepwise acid and alkaline coupling, with the much slower acid coupling being performed first.

Production. 1-Aminonaphthalene-3,6,8-trisulfonic acid (Section 6.6) as the trisodium salt liquor is heated with aqueous sodium hydroxide in an autoclave [7]. The temperature is raised gradually from 150 to 182 °C, and heating is continued until the test for completion (strength by coupling equals strength by diazotization) is satisfied. The melt is diluted, added to excess dilute sulfuric acid, heated at 95 °C to expel sulfur dioxide, cooled, and filtered. The paste is washed and dried for ease of handling. The yield obtained is 72 %.

Given a yield from naphthalene of 62 % for Koch acid, the maximum overall yield of H acid from naphthalene is thus 45 %. Large-scale H

acid production uses naphthalene as starting material, and the through process to Koch acid involves the three process stages of sulfonation, nitration, and reduction. These all require optimization with a view to yield and purity of the ultimate H acid [56]. At the fusion stage, a higher temperature (200 °C) may be used to shorten the reaction period [57]. In a fully integrated process, many of the stage parameters are interrelated [58]. Equally important to the fusion reaction conditions are the work-up conditions to achieve good physical form, a major factor in final quality. The H acid is precipitated as the monosodium salt which has a strong tendency to be thixotropic and is hence difficult to wash.

Uses. Like certain other aminonaphthol derivatives, H acid has been claimed to be a useful corrosion inhibitor. The versatility of H acid as a coupling component is exemplified by alkaline coupling to give monoazo reds such as C.I. Acid Red 33 (**200**) and C.I. Reactive Red 12 (**201**). Even more important, on a volume basis, are disazo blues and blacks such as C.I. Direct Blue 15, C.I. Direct Blue 218, C.I. Acid Black 1, C.I. Direct Black 19, and C.I. Reactive Black 5 (**202**).

200

201

202, X = $SO_2CH_2CH_2OSO_3H$

Some N-substituted derivatives of H acid are isolated for more specialized uses. However, in situ N-acylation is more common with agents such as *p*-toluenesulfonyl chloride or fiber-reactive systems containing an acyl group or equivalent (e.g., as in **201**).

4-Acetylamino-5-hydroxynaphthalene-2,7-disulfonic acid [*134-34-9*] (**203**), *N*-acetyl H acid, is produced by reacting H acid in aqueous alkaline solution with acetic anhydride at 70 °C for 1 h, followed by heating at 95 °C for 2 h to hydrolyze the *O*-acetyl derivative (yield 88 %). It is used to produce C.I. Acid Red 1, C.I. Acid Red 35, and C.I. Acid Violet 7.

203

4-Benzamido-5-hydroxynaphthalene-2,7-disulfonic acid [*117-46-4*] (**204**), *N*-benzoyl H acid, is produced by reaction of H acid with benzoyl chloride in aqueous alkaline sodium carbonate solution at 35 °C for 5 h, followed by heating at 95 °C for 2 h to hydrolyze the *O*-benzoyl derivative (yield 80 %). It is used to produce C.I. Reactive Red 4 and C.I. Direct Green 13.

204

1-Amino-8-hydroxynaphthalene-4,6-disulfonic acid [*130-23-4*] (**167**) (4-amino-5-hydroxynaphthalene-1,7-disulfonic acid), K acid, $C_{10}H_9NO_7S_2$, M_r 319.3: the acid sodium salt of **167** is very soluble in water, but the acid potassium salt is less soluble and is more easily salted out. K acid couples under acid and alkaline conditions in a similar manner to H acid.

Production. 1-Aminonaphthalene-4,6,8-trisulfonic acid paste (Section 6.6) is heated with sodium hydroxide liquor in an autoclave at 170 °C for 12 h, after which the mixture is added to excess dilute hydrochloric acid. After heating to remove sulfur dioxide, the product (including ca. 8 % of the isomeric 5-amino-2-hydroxynaphthalene-4,8-disulfonic acid) is completely precipitated by cooling and is isolated in 86 % yield. Purification of crude K acid may be effected by dissolving it in aqueous alkali and filtering off the less soluble 5,2,4,8-isomer before reprecipitating.

Uses. The N-substituted derivatives of K acid, such as *N*-acetyl, *N*-benzoyl, *N*-(2,5-dichlorobenzoyl), and *N*-benzyl, are used as monoazo coupling components in special cases where an improvement in dye properties over the H acid analogue is demonstrable.

4-Benzamido-5-hydroxynaphthalene-1,7-disulfonic acid [*6361-49-5*] (**205**), *N*-benzoyl K acid, is produced by reacting purified K acid with benzoyl chloride in aqueous alkaline sodium carbonate solution at 35 – 40 °C for 18 h, followed by heating for 1 h at 90 °C to hydrolyze the *O*-benzoyl derivative (yield 80 %). It is used to produce C.I. Acid Red 133, C.I. Acid Red 157, and C.I. Mordant Red 21.

205

2-Amino-5-hydroxynaphthalene-1,7-disulfonic acid [*6535-70-2*] (**168**), sulfo J acid, $C_{10}H_9NO_7S_2$, M_r 319.3.

Production. 2-Aminonaphthalene-1,5,7-trisulfonic acid (Section 6.6) is heated with sodium hydroxide liquor at 170 °C and worked up in a similar way to the K acid. Alternatively, J acid may be sulfonated with 65 % oleum.

Uses. Sulfo J acid is used as a coupling component in azo reactive dyes, e.g., C.I. Reactive Red 6 (the copper complex of **206**).

206

2-Amino-5-hydroxynaphthalene-4,8-disulfonic acid [*74832-35-2*] (**207**) (3-amino-8-hydroxynaphthalene-1,5-disulfonic acid), oxy C acid, $C_{10}H_9NO_7S_2$, M_r 319.3.

Production. 3,8-Diaminonaphthalene-1,5-disulfonic acid (Section 6.8) is monoacetylated in aqueous solution, and the free amino group is diazotized. The diazo compound is added to dilute sulfuric acid at 100 °C to hydrolyze both the diazo and the acetylamino groups [59].

2-Amino-8-hydroxynaphthalene-3,6-disulfonic acid [*90-40-4*] (**169**) (3-amino-5-hydroxy-2,7-disulfonic acid), RR acid, 2 R acid, Columbia acid, $C_{10}H_9NO_7S_2$, M_r 319.3, and its alkali salts are readily soluble in water. Coupling with diazo compounds takes place under alkaline conditions in the position ortho to the hydroxyl group.

Production. 2-Aminonaphthalene-3,6,8-trisulfonic acid liquor (Section 6.6) is concentrated by evaporation and heated with sodium hydroxide liquor in an autoclave [7]. The temperature is raised to 195 °C over 10 h and held at 195 °C for another 8 – 10 h until completion of the reaction is determined by working up a test sample and obtaining a strength by alkaline coupling equal to the diazotization titer. After dilution, acidification, and stirring while hot until all sulfur dioxide is expelled, the product is filtered off as its monosodium salt at 55 °C and washed with brine. Most of the isomeric 2-amino-3-hydroxynaphthalene-6,8-disulfonic acid impurity is removed in the filtrate. Crude RR acid is obtained in 65 % yield and is suitable for certain outlets. Further purification is necessary for critical derived dyes, and this is achieved by dissolving in dilute alkali, filtering at 80 °C, and reprecipitating by addition of sodium chloride and hydrochloric acid. Filtration at 55 °C gives 90 % recovery of product.

Uses. The RR acid is used as a coupling component in azo dyes, e.g., C.I. Food Black 2 and C.I. Direct Brown 151.

1. Introduction

On account of their versatility in application and the excellent fastness of some of them, the naphthalimide dyes have now acquired great industrial importance. They are derivatives of naphthalene-1,8-dicarboximide (naphthalimide) (**1**)[*81-83-4*].

1

Naphthalimide itself is a colorless, crystalline compound, prepared by the oxidation of acenaphthene to naphthalic anhydride [*81-84-5*] [1], followed by conversion to the imide [2].

Naphthalimides only become of interest for color chemistry after substitution with electron-donating groups, preferably in the 4- and 5-positions. The electron-attracting effect of the anhydride or imide group allows the ready exchange of chlorine, nitro, or sulfonic acid groups for alkoxy, aryloxy, amino, and mercapto substituents.

4-Alkoxy- and 4,5-dialkoxynaphthalimides are almost colorless, but are of commercial interest as optical brighteners because of their fluorescence properties (see also → Fluorescent Dyes). The introduction of nitrogen or sulfur in the 4-position gives colored compounds. Together with the perylene-3,4,9,10-tetracarboxydiimides and the perinone dyes, which also belong to the naphthalimide dyes, it is possible to cover the whole color range. The range of applications is very diverse: alongside classical fields, such as dyeing of natural and synthetic textile fibers, plastics, coating and paint pigments, increasingly novel applications are coming to light, in which esthetic considerations are no longer of primary importance. These include, for example, applications in histology for cell staining [3], as laser dyes [4], as the charge-creating layer in electrophotography [5], and in liquid crystal displays [6].

The number of naphthalimide dyes described in the literature is now immense. For this reason it is only possible to describe a few selected types, which have been divided into the following groups on the basis of their structures:

- Alkoxynaphthalimides
- 4-Aminonaphthalimides
- 1′,8′-Naphthoylenebenzimidazoles
- Imides of naphthalene-1,4,5,8-tetracarboxylic dianhydride
- 1′,8′-Naphthoylenebenzimidazole peridicarboximides
- Bis-benzimidazole derivatives of naphthalene-1,4,5,8-tetracarboxylic acid
- 1′,8′-Naphthoylenepyrazoles
- Benzo[*k,l*]xanthene- and benzo[*k,l*]thioxanthene-3,4-dicarboximides
- Azo- and azomethinenaphthalimides
- Perylene-3,4,9,10-tetracarboxydiimides

2. Alkoxynaphthalimides

Naphthalimides with alkoxy substituents in the 4- and 5-positions find application as chlorite-stable optical brighteners. Their relatively low molar extinction coefficients are a disadvantage in comparison with other brighteners. These compounds are produced by reaction of 4-chloro- or 4,5-dichloronaphthalimides with alkoxides. Alternatively, 4-chloronaphthalic anhydride can be treated first with an alkoxide and then with an amine, hydrazine, or hydroxylamine to yield the corresponding imide. The nature of the imide residue determines the field of application. Thus, nonionic naphthalimides such as **2** [*56148-88-0*] are used for brightening polyesters, cellulose acetates, and cotton [7, 8] and also in the base coat of automotive lacquers [9]. Basic cationic naphthalimides such as **3** [*51286-95-8*] are employed for polyacrylonitrile and wool [10, 11].

2

3

ω-Sulfoalkoxynaphthalimides are suitable for brightening synthetic, semisynthetic, and natural fibers. In contrast to most other optical brighteners, which have a red hue, they have a green hue [12].

Another field of application for alkoxynaphthalimides is as electrophotographic toners [13].

3. 4-Aminonaphthalimides

The introduction of an amino group into the 4-position yields brilliant greenish yellow compounds. The usual method of preparation is to treat 4-chloronaphthalic anhydride [*4053-08-1*] with a primary amine to yield the corresponding imide. The nucleophilic substitution with ammonia that follows is frequently carried out under copper catalysis. The arylimides, e.g., the 2′,4′-xylidide (**4**), are commercially important disperse dyes, which, however, can also be employed for coloring plastics or for the production of daylight fluorescent colors [14].

4

Moreover, the corresponding 4-sulfonaphthalimide can also be employed as starting material for the synthesis of 4-*N*-alkylaminonaphthalimides, as illustrated by the example of 4-cyclohexylaminonaphthalene-1,8-dicarboxylic acid *N*-methylimide [*33209-23-3*], which is suitable for dyeing polyesters [15]. Wool, silk, and synthetic polyamides can be dyed in brilliant greenish yellow hues with 4-aminonaphthalimides, but the lightfastness is low. The affinity of the dyes to the fibers is increased by introduction of a sulfonic acid group, preferably in the 3-position. An example of this is Brilliant Sulfoflavin FF (**5**) (C.I. 56 205) [*2391-30-2*] [16], whose further sulfonation in the 6-position leads to a strongly fluorescent, water-soluble dye that can be employed as a biological tracer [3].

5

The usual anchors for reactive dyes, such as the 4,6-dichlorotriazinyl [17] or 2,4-difluoro-5-chloropyrimidyl groups [18], are also encountered in the 4-aminonaphthalimides. The cotton dyes are fast to washing, but as in the examples discussed above are less than satisfactory as far as lightfastness is concerned.

4. 1′,8′-Naphthoylenebenzimidazoles

The reaction of naphthalic anhydrides with *o*-phenylenediamines yields 1′,8′-naphthoylenebenzimidazoles [19]. The 7-*H*-benzimidazo-[2,1*a*]-benz[*d,e*]isoquinolone-(7) framework can also be constructed by first condensing naphthalic anhydride with an 2-nitroaniline and then carrying out ring closure after reduction of the nitro group [20]. Isomers are produced if the aniline or the naphthalic anhydride is substituted, and these can differ in their absorption maxima [21]. Various substituents can also be introduced into the naphthalene moiety by treating 4′-chloro-1′,8′-naphthoylenebenzimidazole with nucleophiles. The 1′,8′-naphthoylenebenzimidazoles are suitable for dyeing polyesters, polystyrene, and other polymers. As a result of their solubility in hydrocarbons, they are also suitable for nondestructive materials testing. The ionic compound **6** [*58888-73-6*], for example, is suitable for polyacrylonitrile fibers, which it dyes in brilliant, lightfast, green-shot yellow hues [22].

6

The polyester dye **7** [*5504-69-8*] is obtained by condensation of naphthalic anhydride with 1,2-diamino-4-methoxybenzene [23].

7

Polyester dyes with brilliant, highly fast, red tones are obtained by annellation of a benzothiophene group [21]. For this purpose, 2-(2-aminophenylthio)-1,8-naphthalic anhydride is diazotized, which results in ring closure to yield benzo[*b*]naphtho[3,2-*d*]thiophen-6,7-dicarboxylic anhydride. Condensation with *o*-phenylenediamine then leads to the dye **8** [*99634-44-3*].

8

In the case of 4-alkylamino substituents, which are introduced by nucleophilic substitution of *N*-methyl-4′-bromo-1′,8′-naphthoylenebenzimidazolium chloride, itis possible to produce brilliant, light-fast polyacrylonitrile dyes, whose color scale ranges from yellow to violet [22].

5. Imides of Naphthalene-1,4,5,8-tetracarboxylic Dianhydride

The simple imides of naphthalene-1,4,5,8-tetracarboxylic dianhydride have no role as dyes because of the lack of a suitable donor – acceptor substitution. The acceptor behavior of the diimide allows electrochemical reduction to complex salts such as **9** [*119298-43-0*], which possesses the surprisingly high conductivity of 7×10^{-3} S/cm [24].

9

6. 1′,8′-Naphthoylenebenzimidazole Peridicarboximides

If naphthalene-1,4,5,8-tetracarboxylic dianhydride is treated first with a primary amine and then condensed with a 1,2-diaminobenzene, a dye of the 1′,8′-naphthoylenebenzimidazole peridicarboximide type is obtained [25]. Originally introduced as vat dyes, they have acquired industrial importance since the appearance of polyester fibers. The most important representatives, which dye in yellow shades, are [26]:

10 $R^1 = CH_3$; $R^2 = CH_3$
[*27767-97-1*]
11 $R^1 = Cl$ $R^2 = (CH_2)_3CH_3$
[*56532-67-3*] [21]
12 $R^1 = CN$ $R^2 = CH_3$
[*22176-47-2*]

7. Bis-benzimidazole Derivatives of Naphthalene-1,4,5,8-tetracarboxylic acid

Naphthalene-1,4,5,8-tetracarboxylic acid can also react on both sides with 1,2-diaminobenzenes. This yields *cis – trans* isomeric mixtures, which are of importance as vat dyes of indanthrene quality and as pigments in the paint industry. In the simplest case naphthalene-1,4,5,8-tetracarboxylic acid is condensed with 1,2-diaminobenzene to give an isomeric mixture of *cis*- and *trans*-**13**.

trans - **13** *cis* - **13**

The two isomers have different color tones and can be readily separated on the basis of their different solubilities, e.g., by recrystallization from sulfuric acid [27, 28], or by formation of an addition complex with potassium hydroxide [29] or 4-toluenesulfonic acid [30]. This yields the isomers Indanthrene Brilliant Orange GR (C.I. 71 105) [*4216-02-8*] and the cis form Indanthrene Bordo RR (C.I. 71 105) [*4216-02-8*].

If 4-chloro-1,2-diaminobenzene or 4-ethoxy-1,2-diaminobenzene is employed in place of 1,2-diaminobenzene, then the products obtained are Indanthrene Printing Brown 5R [*4601-61-0*] or Indanthrene Printing Brown B [*5492-43-2*] [31].

8. 1′,8′-Naphthoylenepyrazoles

Isomeric mixtures also occur in 1′,8′-naphthoylenepyrazoles. Starting from 4-chloronaphthalene-1,8-dicarboxylic hydrazide [*37877-34-2*] [32] a nucleophilic substitution is first carried out at the 4-position, preferably with mercapto or amino groups. Finally, the hydrazone is produced from an acetoacetic acid derivative, which is then cyclized under acidic or basic conditions [33, 34]. Dyes such as **14**, **15** are suitable for synthetic fibers, e.g., polyesters, acetylcellulose and polyamides [33] (see figure on next page).

Other representatives of this group are, for example, the bis-pyrazole derivatives of naphthalene-1,4,5,8-tetracarboxylic acid [35] and the products of the reactions of 4′,5′-dichloro-1′,8′-naphthaloylenepyrazoles with 2-mercaptobenzimidazoles [36].

cis-**14** *trans*-**14** R = −S−

cis-**14** *trans*-**15** R = −N O

9. Benzo[*k,l*-]xanthene- and Benzo[*k,l*-]thioxanthene-3,4-dicarboximides

The starting compounds for this group of dyes are the benzo[*k,l*]xanthene- or benzo[*k,l*]thioxanthene-3,4-dicarboxylic acid anhydrides **16** [*36310-05-1*] and **17** [*14121-49-4*]. To synthesize

16

these compounds, 4-chloro- [37] or 4-nitronaphthalic anhydride [38] is first treated with a 2-aminophenol or 2-aminothiophenol. After diazotization, cyclization to give the heterocycle

17

takes place. An alternative route is the reaction of 4-amino-5-bromonaphthalic anhydride with a phenol. Cyclization to the benzoxanthene also occurs via diazotization [37].

Anhydrides prepared in this manner can be treated with amines [39], diaminobenzenes [37], and hydrazines [40]. They subsequently yield pyrazoles [41] on condensation with acetoacetic acid derivatives. Benzo[*k,l*]thioxanthene-3,4-dicarboxylic acid imides can also be oxidized to the 7,7-dioxides [42]. Structural examples are the compounds **18** [*59373-45-5*] [43], **19** [41], and **20** [*82130-17-4*] [42].

18 **19** **20**

The intense, lightfast, yellow to orange compounds are suitable for the dyeing of polyesters [37,44], mineral oils, thermoplastics [39], polyamides [43], for paint and printing pigments [40], and as liquid crystal dyes [45,46].

10. Azo- and Azomethinenaphthalimides

The azonaphthalimide dyes are generally characterized by good fastness and high thermal stability [47,48]. The absorption maxima of the 3- and 4-substituted compounds can differ by 60 nm. The bathochromic shift upon 4-substitution is attributed to the strong donor–acceptor interaction [49]. Alkaline hydrolysis of 4-halonaphthalimides leads to the corresponding 4-hydroxy derivatives [50], which find application as coupling components. The resulting 3-arylazo-4-hydroxynaphthalimides can be used to dye polyesters [51], polyacrylonitrile [52], polyamides and wool [53], and cellulose [54] in intense, lightfast red tones. Compound **21** [*42358-39-4*] serves as an example of this type of structure.

21

Innumerable examples have been published for the application of 3′-naphthalimido-disazo pigments as the charge-creating layer in electrophotography [55–57].

The 4-arylazonaphthalimides are prepared by diazotization of 4-aminonaphthalimide and coupling to dialkylanilines or heterocycles [47, 58, 59].

The azomethine pigments are obtained by formylation of the reactive 4-hydroxynaphthalimides in the 3-position, followed by condensation with aromatic amines [60, 61].

11. Perylene-3,4,9,10-tetracarboxydiimides

The oxidative dimerization of naphthalimide in molten alkali yields perylene-3,4,9,10-tetracarboxydiimide **22** [62, 63].

Depending on the particle size and the crystalline modification, the product is a violet or red-brown covering or transparent pigment that is principally employed for automotive coatings [64, 65]. In order to synthesize further substituted diimides, perylene-3,4,9,10-tetracarboxylic dianhydride [*128-69-8*] is first prepared by solvolysis in concentrated sulfuric acid [66].

Controlled reaction with primary amines yields monoanhydride-monoimides [67, 68] and the symmetrically and unsymmetrically substituted diimides [69, 70]. The symmetrically substituted diimides have achieved the greatest commercial importance. Depending on their properties they find application as vat dyes of indanthrene quality, highly fast pigments for plastics and coatings, fluorescent dyes with high photostability or as charge-creating layers in electrophotography.

The condensation of perylene-3,4,9,10-tetracarboxylic dianhydride with aliphatic, aromatic, or heterocyclic amines is preferably performed in quinoline with zinc-salt catalysis [71, 72], but is also possible under pressure in aqueous solution [73].

Compounds **22** to **28** have achieved importance as high-quality red pigments. Indanthrene Red LGG (**24**) and Indanthrene Scarlet R (**25**) [74] are valuable vat dyes.

In the case of the perylene-3,4,9,10-tetracarboxydiimides, the crystal structure has a decisive influence on the color. Changing the crystal modification can often bring about improvements in chroma and color intensity [75, 76]. Considerable overlap of molecular stacks, as in **29**, leads to a black coloration. The relationship between crystalline structure and color has been investigated on the basis of several examples [77].

22 R = H (C.I. 71 129) [*81-33-4*]
23 R = CH_3 (C.I. 71 130) [*5521-31-3*]

24 R =  (C.I. 71 135) [*2379-77-3*]

25 R =  (C.I. 71 140) [*6424-77-7*]

26 R =  (C.I. 71 145) [*24108-89-2*]

27 R =  (C.I. 71 155) [*3049-71-6*]

28 R =  (C.I. 71 137) [*4948-15-6*]

29 R =  [*67075-37-0*]

30 R =  [*82953-57-9*]

31 R =  [*83054-80-2*]

The introduction of bulky alkyl substituents results in the formation of soluble fluorescent dyes such **30** [78] and **31** [79]. On account of their high quantum yields and good photostability, they are suitable, when incorporated into glass-clear plastics, for the surface concentration of light and can therefore be employed for fluorescent solar collectors [80]. Good solubility combined with a bathochromic

shift is promoted by donor substitution at positions 6, 7, 12, and 13 of the perylene nucleus [81]. On the other hand, 1,6,7,12-tetrachloroperylene-3,4,9,10-tetracarboxydiimide is a brilliant, weatherproof, red pigment for paints and plastics [82].

The reaction of perylene-3,4,9,10-tetracarboxylic dianhydride with 1,2-diaminobenzenes leads to the corresponding bisbenzimidazoles. They are increasing in importance also in the form of azo pigments in combination with 4-hydroxynaphthalimides as electrophotographic dyes [83–85].

Reaction of perylene-3,4,9,10-tetracarboxylic acid with 4-(2′-hydroxyethoxy)aniline gives a pigment that can be copolymerized with bis(2-hydroxyethyl)terephthalate [86]. Fluorescent red-orange fibers can be produced in this manner.

1. Introduction

Of the five possible naphthoquinones, the isomers (**1**) – (**3**) have been synthesized in a pure form. Of these, 1,4-naphthoquinone (**1**) is produced on an industrial scale as an intermediate for anthraquinone. 1,5-Naphthaquinone (**4**) is known only in the form of its derivatives. The existence of 2,3-naphthoquinone (**5**) was confirmed by trapping it as its Diels – Alder adduct with cyclopentadiene. The synthesis of the unstable 1,7-isomer or of its derivatives has to date not been possible. In contrast, polynaphthoquinone (**8**) is a stable derivative of 1,7-naphthoquinone. The naphthoquinones (**6**) and (**7**) have also been synthesized. The industrially most important compounds are 1,4-naphthoquinone and 2-methyl-1,4-naphthoquinone.

2. 1,4-Naphthoquinone

2.1. Properties

1,4-Naphthoquinone [*130-15-4*], α-naphthoquinone, 1,4-naphthalenedione, M_r 158.16, *mp* 128.5 °C, ϱ 1.42 g/cm^3, crystallizes as yellow needles. It has a penetrating odor, is steam volatile, and sublimes readily. It is insoluble in water but soluble in warm alcohols and hydrocarbons. Phenols and arylamines react at the 2-position. In acids and upon heating it condenses to form oligomers [1] and polymers. Its most important reaction is with butadiene to give tetrahydroanthraquinone, which is oxidized to anthraquinone (see Section 2.3).

2.2. Production

Gas-Phase Oxidation of Naphthalene. The most important process for the production of 1,4-naphthoquinone is the oxidation of naphthalene with air or gases containing molecular oxygen at 250 – 450 °C and 0.1 – 1 MPa, over a catalyst containing vanadium pentoxide.

Kawasaki Kasei Chemicals has been operating an anthraquinone plant with this process in Japan since 1980. Besides vanadium pentoxide, the catalyst also contains potassium sulfate, potassium pyrosulfate, and silicon dioxide [2], [3]. The latter also serves as a carrier and is obtained by treatment of aluminosilicates with acid [4]. As the naphthalene is converted nearly quantitatively, a recycling step is not necessary; 36 mol % of 1,4-naphthoquinone and 54 mol % of phthalic anhydride are obtained.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a17_067

The reaction is best performed under a slightly positive pressure of 0.3 – 0.8 MPa [5]. Although the oxidation is normally carried out in a fixed bed, a flow-bed variant has also been described [6]. Lifetime and selectivity of the catalysts are increased by the addition of sulfur-containing compounds [7]. Phthalic anhydride is always obtained in substantial amounts as a byproduct.

In the Kawasaki process the oxidation product is first treated with water in order to separate the phthalic anhydride as phthalic acid from the reaction mixture [8]. The naphthoquinone is extracted with xylene and the extract washed with dilute alkali to remove residual phthalic acid [9]. Then the naphthoquinone is crystallized from the solvent. High-purity naphthoquinone can be obtained by recrystallizing from xylene [10], or by sublimation [11]. Purification of the quinone can also be achieved by treating the hot xylene solutions with lime [12]. In some applications it is possible to use the crude naphthoquinone in form of the oxidation mixture.

Liquid-Phase Oxidation. 1,4-Naphthoquinone can alternatively be obtained in the liquid phase in greater than 90 % yield by oxidation of naphthalene or its derivatives. The following oxidizing agents have been used on a preparative scale: chromic acid [13], chromium trioxide [14], lead dioxide [15], manganese(II) sulfate [16], ammonium peroxodisulfate [17–19], tetrabutylammonium nitrate in nitric acid [20], and cerium(IV) compounds [21–27]. The oxidation with cerium(IV), in particular, gives high naphthoquinone selectivities, with yields as high as 98 % [23]. Phase-transfer catalysts increase the rate of reaction [19], [20], [27]. Chemical oxidizing reagents can be regenerated electrochemically. The regeneration of cerium(IV) compounds has been extensively investigated in a pilot plant [26]. 1-Naphthol can be catalytically oxidized to 1,4-naphthoquinone with oxygen in the presence of cobalt complexes (Salcomin) in yields of 90 % [28].

2.3. Uses

1,4-Naphthoquinone is industrially significant as an intermediate in the anthraquinone synthesis by Kawasaki (→ Anthraquinone, Chap. 3.3.) [29,30]. Starting from naphthalene, naphthoquinone is obtained by gas-phase oxidation, as described in Section 2.2. In the second step it is converted to 1,4,4a,9a-tetrahydroanthraquinone [*56136-14-2*] with butadiene in a Diels – Alder reaction [29], [30]. The Diels – Alder adduct is extracted as its sodium salt with dilute alkali. Unconverted naphthoquinone in the organic phase is fed back into the Diels – Alder reaction. In the third step the basic tetrahydroanthraquinone solution is oxidized with air to anthraquinone, which forms a precipitate and is filtered off. Kawasaki produces 3000 t/a anthraquinone with this process (→ Anthraquinone, Chap. 3.3.).

In a process developed by Bayer, the 1,4-naphthoquinone is not isolated after the naphthalene oxidation step. Instead, it is reacted with butadiene and oxidized to anthraquinone in the mixture of naphthalene and phthalic anhydride. The products are then separated by distillation [31–34].

1,4-Naphthoquinone has been described as a polymerization regulator [35] and as a hardener for photochemically cross-linked polyesters [36]. It is used as a corrosion inhibitor [37] and as a stabilizer for transformer oils [38]. It reacts with cyclic aryl phosphinic acid esters to give 1,4-naphthalenediol adducts, which can be used for the production of thermally stable, flame-resistant polyesters [39].

2.4. Derivatives

2-Methyl-1,4-naphthoquinone [*58-27-5*], menadione 2-methyl-1,4-naphthalenedione, vitamin K3, M_r 172.20, *mp* 105 – 106 °C is two to three times more effective as a blood coagulator than vitamin K1 (2-methyl-3-phytyl-1,4-naphthoquinone, see → Vitamins). It is obtained from 2-methylnaphthalene in 70 – 90 % yield by oxidation with chromic acid [40], [41]. Slightly lower yields are obtained with chromium trioxide in conjunction with crown ethers [42]. The gas-phase oxidation of 2-methylnaphthalene results in maximally 40 % yields of the quinone [43].

2-Chloromethyl-1,4-naphthoquinone [*43027-41-4*], 2-chloromethyl-1,4-naphthalenedione, and its derivatives are highly potent cytostatic compounds. It is obtained by the oxidation of 2-chloromethylnaphthalene with chromium trioxide [44].

2,3-Dichloro-1,4-naphthoquinone [*117-80-6*], 2,3-dichloro-1,4-naphthalenedione, dichlone, phygon, M_r 227.05, *mp* 193 °C, is an important intermediate in the synthesis of dyes. It can also be converted to pigments of exceptional stability, which are suitable for integration into high performance membranes [45]. It is also used for conserving grain, as an algicide [46], and as an additive in dye binders [47]. This quinone is obtained by oxidation of 4-hydroxynaphthalene-1-sulfonic acid [*84-87-7*] with potassium chlorate in hydrochloric acid [48], or by direct chlorination of 1,4-naphthoquinone [49–51]. Yields of up to 96 % can be obtained by the latter method if the chlorination is carried out in carbon tetrachloride at 50 °C [51].

5-Nitro-1,4-naphthoquinone [*17788-47-5*], 5-nitro-1,4-naphthalenedione, M_r 203.15, *mp* 167 °C, is obtained in 70 % yield by nitration of 1,4-naphthoquinone with a mixture of highly concentrated nitric and sulfuric acid [52]; 6-nitro-1,4-naphthoquinone [*58200-82-1*] is formed as a byproduct. Nitronium tetrafluoroborate ($NO_2^+BF_4^-$) is also a suitable nitrating reagent [53]. The 5-nitro-1,4-naphthoquinone is also accessible by the electrochemical oxidation of 1-nitronaphthalene in a mixture of a mineral acid and a water-soluble organic solvent [54]. Nearly quantitative yields can be obtained through the reduction of 5-nitro-1,4-naphthoquinone monooxime with sulfur dioxide and phosphorus in the presence of hydrogen iodide, followed by oxidation of the resulting isomeric 1-aminonitronaphthols [55].

The reaction of 5-nitro-1,4-naphthoquinone with butadiene and subsequent oxydehydrogenation leads to 1-nitroanthraquinone [*82-34-8*] [56–58], which is the precursor of the important dye intermediate 1-aminoanthraquinone [*25620-59-1*].

Hydroxy Derivatives. A few monohydroxy derivatives of 1,4-naphthoquinone occur in nature as dyes in plants: for example, 5-hydroxy-1,4-naphthoquinone [*481-39-0*] (juglone) and 2-hydroxy-1,4-naphthoquinone [*83-72-7*] (lawsone). 2-Alkyl-3-hydroxy-1,4-naphthoquinones are used as antimalarial agents [59] and insecticides [60]. Derivatives of naphthazarin (5,8-dihydroxy-1,4-naphthoquinone) [*475-38-7*] are dyes (vat dyes, alkannins). Naphthazarin can be made from 1,5-dinitronaphthalene [*605-71-0*] by conversion with sulfur and sulfuric acid [61] via the intermediate 5-hydroxy-8-amino-1,4-naphthoquinone [*68217-36-7*]. Alternatively, it can be prepared from the reaction of dichloromaleic anhydride [*1122-17-4*] with 1,4-dimethoxybenzene [62]. The resulting 2,3-dichloronaphthazarin [*14918-69-5*] is converted to 2,3-dihydronaphthazarin [*4988-51-6*] with tin(II) chloride in hydrochloric acid in the second step and then converted to naphthazarin in alkaline solution with an overall yield of 66 %.

3. Other Naphthoquinones

1,2-Naphthoquinone [*524-42-5*], α-naphthoquinone, 1,2-naphthalenedione, M_r 158.16, *mp* 145 – 147 °C, crystallizes as yellow needles, is odorless, is involatile in steam, and is a relatively weak oxidizing agent. It is obtained in 80 % yield when 2-naphthol is oxidized by air in the liquid phase with copper(I) chloride as catalyst [63]. Slightly lower yields are obtained when periodic acid and dimethyl formamide [64], iodosobenzene [65], or benzene seleninic anhydride is used as oxidant [66]. A 95 % yield can, however, be obtained with tetramethyloxopiperidinium chloride [*26864-01-7*] at low temperature [67]. The quinone can also be obtained by the oxidation of 1-amino-2-hydroxynaphthalene hydrochloride [*1198-27-2*] with iron(III) chloride in hydrochloric acid [68].

Only the derivative 6-bromo-1,2-naphthoquinone [*6954-48-9*] (bonaphthon), which exhibits activity against type A influenza viruses, is of any practical interest [69].

2,6-Naphthoquinone [*613-20-7*], M_r 158.16, *mp* 135 °C (decomp.), forms red prisms. It is a stronger oxidizing agent than the other naphthoquinones. It is obtained by the oxidation of 2,6-naphthalenediol [*581-43-1*] with lead dioxide in benzene [70].

1,5-Naphthoquinone [*51583-62-1*] is not known in the pure form. Its derivative, 3,7-di-*t*-butyl-1,5-naphthoquinone [*54532-93-33*], is obtained in virtually quantitative yield by oxidizing the corresponding hydroquinone with dichlorodicyano-*p*-benzoquinone [71]. The naphthazarin isomer 4,8-dihydroxy-1,5-naphthoquinone [*6251-03-2*] is a starting material for thermally stable dyes [72].

2,3-Naphthoquinone [*4939-92-8*] has also not been isolated. The existence of this unstable quinone was verified by trapping it as the Diels – Alder adduct with cyclopentadiene during the oxidation of 2,3-naphthalenediol with potassium periodate [73].

1,7-Naphthoquinone [*46001-16-5*] is also very unstable and has not been isolated. The derivative, 3,6-di-*t*-butyl-8-methyl-1,7-naphthoquinone [*83021-64-1*], can be obtained in impure form in solution during the oxidation of the corresponding hydroquinone with dichlorodicyano-*p*-benzoquinine [74].

4. Naphthodiquinones

1,2,3,4-Naphthodiquinone [*30266-58-1*], 1,2, 3,4-naphthalenetetrone, oxolene, M_r 188.10, *mp* 131 °C, ϱ 1.45 g/cm^3, forms colorless crystals. It is obtained from 2,3-dihydroxy-1,4-naphthoquinone through oxidation with nitric acid in glacial acetic acid [75].

1,4,5,8-Naphthalenetetrone [*23077-93-2*], M_r 188.10, *mp* 220 °C, ϱ 1.45 g/cm^3, is obtained as pale yellow prisms by the oxidation of 5,8-dihydroxy-1,4-naphthoquinone with lead tetraacetate [76] or with iodophenyl-bis(trifluoroacetate) in 81 % yield [77].

5. Polynaphthoquinone

Polynaphthoquinone [*38830-94-3*], 1,7-naphthalenedione polymer, is a black powder which melts above 360 °C and sublimes at 450 °C. It is made by oxidizing 1,7-naphthalenediol [*575-38-2*] with dilute nitric acid in ethanol, followed by heating in a stream of air at 350 °C [78], [79]. The polyquinone is suitable as a catalyst for the oxydehydration of alkanes, alkenes, and alcohols. Its reactivity can be greatly enhanced through the addition of Lewis acids [78], [79].

Natural gas is a mixture of gaseous hydrocarbons with impurities mainly made of nonhydrocarbons. It occurs in subsurface deposits of many geologic formations. Natural gas is recovered with wells that are drilled into these deposits and is produced at the well site in compositions of considerable variety. The most important method for chemical analysis of natural gas is gas chromatography. The *Wobbe index* is the most important physical characteristic for the classification of natural gases. Natural gas is primarily employed as clean heating fuel in industry, power plants, commercial installations, and households. The objectives of natural gas treating are the adjustment to the required quality standards and the recovery of byproducts. Removal of the sour gas components hydrogen sulfide and carbon dioxide is one of the most common aims of natural gas treating. Of the gas traded across international borders, 75 % is shipped by pipelines, and 25 % is carried by liquified natural gas tankers. A large share of internationally traded natural gas is normally sold by producers under long-term contracts of up to 35 years' duration in order to compensate for the heavy front-end investment in production, purification, and transportation facilities.

1. Introduction

Natural gas is a mixture of gaseous hydrocarbons with varying quantities of nonhydrocarbons, which are normally considered impurities. Natural gas is often associated with liquid hydrocarbons (i.e., condensate and crude oil).

Natural gas formed during many epochs in the history of earth and accumulated after migrating from its place of origin to subsurface deposits in porous or fractured layers of many geologic formations (→ Oil Refining). Natural gas is recovered with wells that are drilled into these deposits. Worldwide annual production amounts to ca. 2.8×10^{12} m^3. Estimated gas reserves are on the order of 150×10^{12} m^3 (see Chap. 5).

1.1. Composition

Usual Composition. Natural gas is composed mainly of methane, ethane, propane, and butane. In addition, it usually contains minor quantities of heavier hydrocarbons and varying amounts of gaseous nonhydrocarbons such as nitrogen, carbon dioxide, and hydrogen sulfide. A typical composition is given in Table 1.

Table 1. Typical composition range of natural gas

Compound	Molar fraction
Hydrocarbons	
Methane	0.75 – 0.99
Ethane	0.01 – 0.15
Propane	0.01 – 0.10
n-Butane	0.00 – 0.02
Isobutane	0.00 – 0.01
n-Pentane	0.00 – 0.01
Isopentane	0.00 – 0.01
Hexane	0.00 – 0.01
Heptane plus higher hydrocarbons	0.00 – 0.001
Nonhydrocarbons	
Nitrogen	0.00 – 0.15
Carbon dioxide	0.00 – 0.30
Hydrogen sulfide	0.00 – 0.30
Helium	0.00 – 0.05

Main Impurities. In many areas the natural gas recovered is *sour*, which means that it contains appreciable quantities of hydrogen sulfide and carbon dioxide. Although larger quantities of carbon dioxide are undesirable because they make the transport of natural gas more costly, diminish its combustion qualities, and have a corrosive effect under certain conditions, carbon dioxide can be tolerated in percentage levels. In contrast, hydrogen sulfide concentrations in salable gas must be reduced below 3 ppm because of its high toxicity. Furthermore, it is very corrosive in combination with water and, when burned, produces sulfur dioxide, which is also toxic and corrosive. Therefore, sour gas is generally desulfurized or *sweetened* to reduce the hydrogen sulfide content to traces (clean gas).

Higher Hydrocarbons and Water Vapor. Natural gas may contain larger quantities of higher hydrocarbons than shown in Table 1 (so-called *rich* or *wet* gas) and, in addition, is saturated with water vapor under natural conditions. These constituents can condense at lower temperature and higher pressure and thereby impair the transport and use of natural gas. Under certain conditions, water and gas can form icelike solids, so-called hydrates (see Section 1.2). Therefore, the proportion of condensable constituents is normally decreased substantially by refrigeration, adsorption, or absorption processes before the natural gas (then called *lean* or *dry* gas) is transmitted through pipelines or liquefied.

1.2. Physical Properties

Molar Mass. Table 2 shows the molar mass of the commonly occurring components of natural gases. The apparent molar mass M_a of a gas mixture such as natural gas is equal to the sum of the molar fraction y_i times the molar mass M_i of each component:

$$M_a = \Sigma y_i M_i \tag{1}$$

Molar Volume and Ideal-Gas Law. The volume occupied by an ideal gas depends on the temperature, pressure, and number of molecules present. It does not depend on the type of molecules (ideal-gas law).

The volume of 1 kmol of an ideal gas at STP (273.15 K, 0.101325 MPa) can be calculated, by using the ideal-gas law, to be 22.414 m^3. The effective molar volumes at STP for common natural gas components are shown in Table 2. The calculation may also be employed for gas mixtures if the apparent molar mass, $M_a = \sum y_i M_i$, is used in computing the number of kilomoles n.

Density and Relative Density. The density of several components of natural gas is given in Table 2. The density of a gas mixture can be calculated by the same procedure described in Equation (1). For deviating temperature and pressure conditions, or when the ideal-gas law cannot be applied, the density of a gas under any conditions can be calculated from the real-gas law:

$$pV = znRT \tag{2}$$

where z is the so-called compressibility factor (see page 5).

With Equation (2) the density of a gas can be calculated from the relationship

$$\varrho = pM/zRT \tag{3}$$

where V and n in Equation (2) are replaced by

$$\varrho = nM/V \tag{4}$$

For a gas mixture such as natural gas, the molar mass M in Equation (3) is replaced by the apparent molar mass, M_a, and z is the compressibility factor of the gas mixture at the temperature and pressure conditions of interest.

The *relative density d* (see Table 2) (traditionally designated specific gravity) of a gas is the ratio of its density to the density of dry air at standard conditions:

$$d = \frac{\varrho_{gas}}{\varrho_{air}} \tag{5}$$

For a gas mixture, the relative density can also be calculated from the apparent molar mass M_a of the gas mixture divided by the molar mass of air (28.963):

$$d = \frac{M_a}{28.963} \tag{6}$$

Critical Temperature and Pressure of Natural Gas Components. The critical temperature T_c is the temperature above which a gas cannot be liquefied even if high pressure is applied. At the critical temperature a gas can be liquefied by application of a certain minimum pressure, the critical pressure p_c. The volume of 1 kg of a gas at this critical point is the critical volume V_c; the reciprocal value of V_c is the critical density ϱ_c.

The critical constants for the primary constituents of natural gases are given in Table 3. The critical temperature and pressure are constants for each species.

Principle of Corresponding States. Properties of gases can be correlated if they are compared at "corresponding" values of absolute temperature and pressure. The critical state of a gas is used as reference point, and so-called reduced values are obtained. The following terms are employed:

$$p_r = p/p_c, T_r = T/T_c, \text{ and } V_r = V/V_c$$

Table 2. Physical properties of natural gas components at STP [4]

Compound	Molar mass M, kg/kmol	Molar volume V, m^3/kmol	Density ϱ, kg/m^3	Relative density d (air = 1)
Methane	16.043	22.360	0.7175	0.5549

Nitrogen	3.39	−146.95	3.1949	313
Carbon dioxide	7.38	31.05	2.1359	468
Hydrogen sulfide	8.94	100.05	2.8903	346
Helium	0.227	−267.96	14.3143	69.9

where T_c, p_c, and V_c are the critical point conditions, and T, p, and V are the values of the system, respectively.

If the principle of corresponding states is applied to a mixture of gases, "pseudocritical" temperatures and pressures are defined as the molar average critical temperatures and pressures of the components:

$$p_{pc} = \sum y_i p_{ci}$$

$$T_{pc} = \sum y_i T_{ci}$$

where the subscript pc designates the pseudocritical values of the gas mixture, *ci* the critical values of the components, and y_i is the molar fraction of component *i*. The pseudocritical pressure and temperature are then used to determine the pseudoreduced conditions:

$$p_{pr} = p/p_{pc}$$

$$T_{pr} = T/T_{pc}$$

Although they are convenient for correlating purposes the pseudocritical values have no physical significance.

Viscosity. For an ideal gas, the pressure and temperature dependence of viscosity is opposite to that of liquids; the viscosity of an ideal gas increases with increasing temperature and is independent of pressure. Actual hydrocarbon gases, however, deviate from ideal behavior and approach that of liquids; their viscosity increases with increasing pressure, and decreases with increasing temperature at intermediate or high pressure.

Figure 1 is employed for estimating the dynamic viscosity u_{ga} of natural gases composed

primarily of hydrocarbons at atmospheric pressure [6]. The presence of carbon dioxide, hydrogen sulfide, and nitrogen increases the viscosity. The viscosity u_g at any desired temperature and pressure can be obtained from Figure 2, where the ratio u_g/u_{ga} is plotted as a function of the pseudoreduced temperature and pressure.

Figure 1. Viscosity of paraffin hydrocarbon gases at 101.3 kPa as a function of molar mass [6]
[(°F−32)/ 1.8 = °C] (Copyright Society of Petroleum Engineers, 1954)

Figure 2. Viscosity ratio as a function of pseudoreduced temperature [6] (Copyright Society of Petroleum Engineers, 1942)

Compressibility of Real Gases. At higher pressure the attractive or repulsive forces between gas molecules become important because the molecules possess finite volumes. The assumptions for ideal-gas behavior are then no longer valid; consequently, the real-gas law (Eq. 2) was formulated by introducing a proportionality term (the compressibility factor) to the ideal-gas law. Compressibility factors for natural gases are determined by laboratory measurements, estimated by correlations, or calculated by equations of state.

Figure 3, which was developed by Standing and Katz [7] from data collected on methane and natural gases in the range of up to 56 MPa and 121 °C, presents a correlation between compressibility factors and pertinent pseudoreduced temperatures and pressures. Correlations are also available for pressures and temperatures above these ranges [2, 3].

The specific $p - V - T$ relationship of fluids is described mathematically by equations of state. These equations number in the hundreds, ranging from those for a specific pure compound to generalized forms that claim to relate the properties of multicomponent mixtures. Well-known examples are the *van der Waals equation* [8] with the modifications of Redlich and Kwong [9], Soave [10], and Peng and Robinson [11] and the *virial equation*. The van der Waals type of equation of state can be solved directly for the compressibility factor z. The most reliable methods for typical natural gases are those of Robinson and Jacoby [12], and Hall and Yarborough [13].

Well-known *virial equations* are the *Benedict – Webb – Rubin* equation [14] and the *Starling – Hon* [15] extension of the Benedict – Webb – Rubin equation. The European Gas Research Group (GERG) and the van der Waals Institute at Amsterdam carried out an extensive research project [16] to develop a virial equation of state for the accurate prediction of compressibility factors for natural gas mixtures. They used the virial equation solved for the compressibility factor z and truncated after the third term:

$$z = 1 + B(T)\,\varrho_M + C(T)\,\varrho_M^2$$

where ϱ_M is the molar density, $\varrho_M = 1/V_M$, and B and C are the second and third virial coefficients, which depend on temperature and gas composition. With this equation, compressibility factors can be predicted within the range 0 to 12 MPa and −8 to 62 °C, which deviate $<$ 0.1 % from experimental data.

Figure 3. Compressibility factor of natural gases as a function of pseudoreduced pressure and temperature [7] (Copyright Society of Petroleum Engineers, 1942)

Condensation Behavior of Heavier Hydrocarbons.

Phase Diagram. Figure 4 shows the phase diagram of a natural gas system. It represents the phase changes with temperature and pressure for a particular constant composition, and designates the pressure and temperature regions in which only gas or liquids can occur and those in which they coexist at equilibrium. The two-phase region or "envelope" is enclosed on the left side by the bubble point curve up to the critical point C and from there on, via the points of maximum pressure C_p and maximum temperature C_T, by the dew point curve.

The bubble point curve designates the points at which the first infinitesimal bubble of gas is formed from the liquid phase, and the dew point curve indicates the points at which the first infinitesimal drop of liquid condenses from the gaseous phase. The critical point C (juncture of bubble and dew point curves) is the point at which all intensive properties of gas and liquid phases are identical. The pressure p_c and the temperature T_c at this point are the critical values of the gas mixture. The *cricondenbar* point C_p is defined as the maximum pressure at which two phases can exist in equilibrium. In natural gas systems this point lies right of the critical point C. The *cricondentherm* point C_T is defined as the maximum temperature at which two phases can exist in equilibrium.

Figure 4. Phase diagram of a hydrocarbon system of fixed composition

Retrograde Condensation. The dashed lines within the two-phase envelope of Figure 4 are liquid-content lines commonly represented by volume percent liquid lines. They originate at the critical point C and are intersected by a line connecting the critical point C with the maximum temperature point C_T. This line separates the two-phase envelope in two regions. In the lower region the gas mixture behaves as expected: At constant or decreasing temperature, the liquid content in the gas mixture increases with increasing pressure. The behavior of the gas mixture in the two-phase region above the connection line $C - C_T$ is quite different. At constant temperature, the liquid content in the gas mixture increases with decreasing pressure, and in the range between the critical pressure and the maximum pressure, the liquid content increases at a pressure drop even when the temperature increases.

This phenomenon, called *retrograde condensation*, may seriously impair the transport of natural gas through pipelines because liquid slugs can be formed if the higher hydrocarbons have not been removed sufficiently. The condensation behavior of natural gas can be determined by employing equations of state or by laboratory measurements [17].

Gas Hydrates. Gas hydrates are icelike solids composed of water and hydrocarbons. Hydrocarbons ranging from methane to cyclopentane are known to form hydrates. The formation of hydrates depends on pressure, temperature, molecular size, and concentration of the component. Generally, hydrates form at high pressure and low temperature, but they can occur as high as 30 °C and below 0.7 MPa. Hydrate formation can be predicted from empirical vapor – solid equilibrium ratios, empirical correlations, and laboratory measurements [18].

To avoid the formation of gas hydrates in pipelines, the water vapor content of natural gas is commonly reduced by dehydration before transport. Lowering the water dew point to −5 to −8 °C in relation to the maximum transmission pressure, is a common stipulation in gas specifications.

1.3. Combustion Properties

1.3.1. Calorific Value

The calorific or heating value of natural gas is defined as the heat evolved by complete combustion of a unit quantity of dehydrated gas with pure oxygen at 0.101325 MPa. The initial temperature of gas and oxygen is 25 °C. The flue gas resulting from the combustion process is cooled to the same temperature.

In determining the *total calorific value*, also called the *gross calorific value* (higher heating value), all the water formed in the combustion process is condensed to the liquid state. For determination of the net calorific value (lower heating value), all the water formed by the combustion reaction remains in the vapor state: i.e., the gross and net calorific values differ in the condensation enthalpy of water. The calorific value is expressed in megajoules per cubic meter or, occasionally, kilowatt-hours per cubic meter.

Calorific Value of Gas Mixtures. The calorific value of natural gas can be calculated from the molar composition and the calorific values of the components:

$$H = \sum y_i H_i$$

where y_i is the molar fraction of component i, H_i is the gross or net calorific value of component i. Table 4 shows calorific values for commonly occurring components of natural gas.

Table 4. Calorific values of natural gas components at STP [19]

Compound	Gross calorific value, MJ/m^3	Net calorific value, MJ/m^3
Methane	39.819	35.883
Ethane	70.293	64.345
Propane	101.242	93.215

n-Heptane	265.22 *	245.99 *
Hydrogen sulfide	25.336	23.353

* Compound is in liquid state at STP.

1.3.2. Wobbe Index

When burned at the same pressure, natural gases with different compositions generate the same amount of heat per time unit if their calorific values divided by the square root of their relative densities (Wobbe index) are equal. The Wobbe index can be referred to the gross or net calorific value:

$$W_{\text{gross,net}} = H_{\text{gross,net}} / \sqrt{d}$$

Since gas burners tolerate only limited fluctuations in the heating value of fuel gas, these fluctuations must be restricted. Therefore, natural gas specifications generally stipulate ranges that are defined by Wobbe index rather than heating values [20]. Consequently, certain gas streams may require blending before sales, or separate pipeline networks may be operated on different gas streams with deviating Wobbe index levels.

2. Treating

Natural gas is produced at the well site in compositions of considerable variety. The objectives of natural gas treatment are correspondingly diverse. The composition range that must be encompassed is shown in Table 5 for selected examples.

Besides its primary constituent methane, natural gas may contain various amounts of impurities, which lead to varying problems during production and transportation:

Water. Condensed water forms solid hydrates with hydrocarbons or hydrogen sulfide, or in addition leads to liquid slugs in pipelines and to corrosion [21].

Higher Hydrocarbons. If natural gas contains higher concentrations of C_{2+} hydrocarbons, the recovery of liquid petroleum gas (LPG) and gas condensate is economically important. The desired Wobbe index (see Section 1.3.2) and calorific value could also require a reduction in the concentration of higher hydrocarbons. Even very low concentrations of higher hydrocarbons can condense in pipelines (retrograde condensation). These condensed hydrocarbons can attack plastic pipes and control devices.

Hydrogen Sulfide. Hydrogen sulfide together with free water can cause corrosion, particularly stress corrosion and hydrogen-induced cracking. Removal of hydrogen sulfide is performed almost exclusively in centralized treatment plants.

Carbon Dioxide. Carbon dioxide together with free water causes pitting corrosion in carbon and low-alloy steels. Some natural gases that contain significant amounts of CO_2 must be treated to increase the methane concentration prior to sales.

Sulfur. Gases containing hydrogen sulfide can also contain elementary sulfur as vapor. Some gas fields, primarily in Canada, Germany, and the United States, contain such high quantities that the sulfur, depending on pressure, temperature, and gas composition, can precipitate and plug the production pipe, which then becomes blocked. Furthermore, elemental sulfur and free water are corrosive.

Mercury. Natural gas can contain mercury in concentrations up to several milligrams per cubic meter, the bulk of which exists in elemental form. Separated liquid mercury causes mercury-induced corrosion in pipes and fittings, corrosion damage to aluminum heat exchangers in cryogenic plants, and damage to measuring and control valves containing nonferrous metals by amalgam formation. Mercury must also be removed because of its toxicity.

Table 5. Composition of natural gas

Source	Methane, vol %	Ethane, vol %	Propane, vol %	Butane, vol %	Higher hydrocarbons, vol %	Nitrogen, vol %	Carbon dioxide, vol %	Hydrogen sulfide, vol %	Elemental sulfur, g/m^3	Organic sulfur, ppm	Helium, vol %	Mercury, mg/m^3

[a] Sweet gas with low calorific value, only adjustment of water dew point.
[b] Natural gas with high calorific value, H_2S conversion to COS at molecular sieve.
[c] Mercury removal, C_{3+} separation by low temperature separation and adsorption.
[d] Liquefaction, separation of gas condensate, $CO_2 - H_2S - Hg$ removal.
[e] Helium production.
[f] Nitrogen separation, CO_2 removal.
[g] Sour gas, use of sulfur solvent, H_2S, CO_2 scrubber, sulfur production.
[h] Condensate, LPG, sulfur recovery, removal of organic sulfur compounds.
[i] Ultrasour gas, only for sulfur production.

Other Components. In Alabama, for example, *cyclic hydrocarbons* such as adamantane and diamantane are found in natural gas; these compounds are inclined to sublime and must be removed by injection of oil.

Some gases contain high amounts of *nitrogen*, which must be separated to obtain a sales gas with the required combustion properties.

Recovery of Components with Economic Value. Another important factor is whether additional components must be removed to meet product specifications, or whether the recovery of these products is of economic interest. Examples of the latter include the recovery of helium, the production of sulfur from sour gas, and the recovery of LPG and hydrocarbon condensates. A special case is so-called *ultrasour gas* (see line 9 of Table 5). In this case the main interest is not to produce a fuel gas but rather to provide a feedstock in the production of sulfur. In Canada, production of gas with a hydrogen sulfide content of 90 % began. In addition, the removal of carbon dioxide for enhanced oil recovery in crude oil production should be mentioned.

By contrast, if these components are present only in trace amounts they are not removed because of economic reasons, but rather to avoid corrosion, environmental, or production problems.

The individual process by which undesired gas contaminants can be eliminated depends on the composition of the gas, the amount and type of contaminant, and ultimately whether a salable pure gas must be delivered at the well or whether the gas is piped to a processing plant.

2.1. Objectives of Natural Gas Treating

Two objectives must be met in treating natural gas:

- Adjustment to the required quality standards
- Recovery of byproducts

The main objective worldwide is production of a sales gas of pipeline standard. In this respect, both the extent of removal of undesirable components and the range of conditioning measures are predetermined.

Natural gas treating can take place both directly *at the well* and in *centralized plants*. Treating at the well is always necessary when the gas cannot be transported to a processing plant by pipeline without hazard. To avoid corrosion, sour gas is often dehydrated at the well so that free water can no longer condense in the pipeline. The recovery of sulfur and the separation of nitrogen, carbon dioxide, or helium are carried out in centralized plants, to which streams of different wells are fed. The same holds true for liquefaction of natural gas, recovery of LPG, and removal of higher hydrocarbons.

2.2. Natural Gas Wells and Field Installations

Installations at individual gas wells must fulfill the following objectives:

to guarantee trouble-free gas flow in the production pipes and surface equipment;
to separate or, if necessary, treat coproduced liquids;
to condition the gas for transportation to the processing plant;
to meet the required feed quality for the pipeline distribution network; and
to protect the production pipes and field installations from corrosion.

The type and design of plants are determined by:

type and concentration of accompanying substances in the gas;
behavior of the gas during pipeline transportation; and
applicable sales specifications.

Basic Flow Diagram of Natural Gas Treating. A flow diagram for the most important treatment steps is shown in Figure 5. To prevent deposition of *elemental sulfur*, which can occur, for example, in some sour gas wells, solvents are pumped into the production pipe. Corrosion inhibitors can also be introduced in the same way. On the surface, liquids condensed under the well-head flow conditions are separated. After being depressurized and cooled to collection pipe conditions, further condensate is precipitated. If necessary, separated condensate must be treated further (phase separation, stabilizing, stripping). If large amounts of formation water occur or considerable amounts of liquids (inhibitors, sulfur-dissolving agents) are injected during sour gas production, hydrogen sulfide may be released during depressurization and transportation of these liquids. Emissions can be minimized by high-pressure liquid stripping or by recompression of the flashed gas. When no further condensable hydrocarbons are present, the gas is dehydrated to a dew point equal to or below the dew point specified for pipeline transportation.

Whereas *sweet gas* can be fed directly from the well site to the distribution network, *sour gas* is usually treated further in a centralized plant serving several gas fields. If pressure at the production well is low, compressors are installed upstream of the pipeline network or treatment plant.

For wet gases (see Section 1.1), both the dew point of hydrocarbons and that of water must be lowered. After the injection of hydrate inhibitors (e.g., glycols, methanol), water vapor and higher hydrocarbons are condensed by reducing the temperature [22].

If reduced pressure in the downstream pipeline system causes retrograde hydrocarbon condensation, adsorption processes are used for further removal of higher hydrocarbons [23].

Various adsorbents are available to remove traces of mercury; activated charcoal impregnated with sulfur is particularly useful.

2.3. Processing Steps During Production

2.3.1. Use of Sulfur Solvents

If elemental sulfur is present in the reservoir, sour natural gases are enriched with sulfur to a greater or lesser extent. The ability of the gas to absorb sulfur depends strongly on pressure, temperature, and gas composition [24]. Cooling and pressure reduction during production minimize the solubility of sulfur and lead to its precipitation; at low temperature, solidification and blockage of the pipe may occur. These problems are generally overcome by injection of suitable solvents into the production equipment which permits sulfur to be removed with the injected

Figure 5. Treating of natural gas
—— Flow sheet for treatment of sweet gas
– – – Additional steps required for treatment of sour gas

liquid, either chemically bound or physically dissolved. Two different reliable processes are applied:

Polysulfide Process [25]. By the addition of aqueous ammonia or monoethylamine solutions, sulfur is dissolved, in the presence of hydrogen sulfide, as polysulfide and separated at the surface in a liquid separator. The sulfur-laden liquid can be regenerated at ca. 150 °C. Ammonia or amine, water, hydrogen sulfide, and carbon dioxide are dissolved in the condensed water and reinjected into the well. Sulfur is precipitated as a liquid and removed from the bottom of the regenerating column.

With this process, only a single liquid phase occurs above ground. Traces of ammonia or amine cause no problems in the downstream treatment. For gases with a high carbon dioxide content the process can be employed only under certain conditions. In this case the alkaline media cannot dissolve sufficient hydrogen sulfide for the formation of polysulfide. This solvent also cannot be employed in the presence of formation water containing alkaline-earth metal chlorides because the calcium carbonate and magnesium hydroxide formed cause blockages that can be dissolved only by acid treatment. Specific measures are necessary to prevent down-hole tubing corrosion.

Physical Solvents [26]. In the production of sour gas, sulfur may also be physically dissolved by means of suitable hydrocarbons. A suitable solvent must have the following properties:

no reaction with formation water;
stability under reservoir conditions;
no reaction with sulfur;
high solvent power for sulfur;
very low vapor pressure; and
noncorrosiveness.

Spindle oil and mixtures of spindle oil with special aromatic coal tar fractions, which have a very high solvent power for sulfur, are the most common solvents for this purpose. These oils simultaneously serve as carriers for corrosion inhibitors.

Sulfur-laden oils can be regenerated, for example, by extraction with amine solutions that also contain hydrogen sulfide. After removal of sulfur by formation of polysulfides these solutions can be regenerated as already mentioned. Phase separation may be hindered by formation of emulsions of the oil with the simultaneously separated water, making specific measures necessary.

Typical concentric piping for sour gas production is shown in Figure 6, in which the solvent is pumped into the well through the outer concentric pipe and returns to the well head with the gas production stream. A sour gas well with solvent injection and the necessary regeneration plant is depicted schematically in Figure 7.

2.3.2. Removal of Mercury

Natural gas from predominantly "Rotliegenden" reservoirs often contains mercury in vapor and/or aerosol form [27]. Natural gas fields containing mercury are known in Algeria, Indonesia, The Netherlands, and the Federal Republic of Germany. Mercury has not resulted in any problems in production from sour gas fields. To avoid health hazards during treatment and use, the mercury content is lowered in separate mercury-removal plants from 5 mg/m^3 to < 10 µg/m^3.

A considerable portion of the mercury has often already been removed by low-temperature separation (LTS) in the dehydration unit at the well. Mercury levels of < 5 µg/m^3 are attained in downstream chemisorption fixed-bed reactors with, for example, sulfur-impregnated activated carbon. Condensable components, such as water or hydrocarbons, reduce the loading ability for mercury or even deactivate the adsorbent. The reactors are not regenerated; rather, the laden adsorbent is fed to an external treatment plant. Regenerative amalgamation processes are currently being tested.

Figure 6. Schematic of a typical sour gas well completion a) Well head; b) Anchor casing; c) Cement; d) Intermediate casing; e) Injection annulus; f) Tubing; g) Production packer; h) Liner; i) Perforations

Mercury is also collected from the liquid hydrocarbon stream by phase separation. Further treatment with solid adsorbents reduces the mercury content from 300 to 20 ng/g.

2.3.3. Dehydration

In most cases, natural gas is dehydrated close to the gas wells for safety reasons. The formation of gas hydrates in high-pressure gas pipelines can thus be avoided and problems arising from liquids in the transportation system minimized. In general, a water dew point of −8 °C at the pipeline pressure is adequate. In particular, in the presence of carbon dioxide, hydrogen sulfide, and chlorides, corrosion can be minimized by decreasing the water content. In some gas fields, dehydration is not employed; production is maintained by the use of specific corrosion-resistant materials together with corrosion inhibitors and thermally insulated equipment.

Cryogenic Dehydration. To decrease the higher hydrocarbon content in addition to maintaining a specific water dew point, cryogenic dehydration of natural gas is often employed (see Fig. 8). The wet gas is cooled until the components to be removed precipitate by condensation or formation of hydrates. Methanol, glycol, or a paraffin solvent is often also injected. The reduction in temperature can be achieved by Joule – Thomson expansion. This route is employed particularly in the first phase of production in high-pressure wells. When the production pressure is close to that of the transportation system, external cryogenic units are used.

Dehydration by Absorption Processes [28]. Standardized dehydration plants using glycol absorption are employed most widely. Triethylene glycol (TEG) is used in preference to other glycols (mono- and diethylene glycols) because of its high absorption capacity for water vapor, its low vapor pressure (small losses from evaporation), and its high thermal stability. This type of dehydration plant is shown in Figure 9.

In the absorber (h), glycol and gas are brought in contact countercurrently. Plant pressures of 2 – 10 MPa are typical.

In the approximately pressureless *regeneration* step, water-laden glycol is heated to 200 °C. The energy requirement is reduced by extensive heat exchange between laden and regenerated glycol in a coiled tube in the storage vessel and in the top of the regeneration column. Both direct gas-fired regenerators and those with steam or electric heating are used. The residual water content (ca. 1 %) in the glycol after thermal regeneration can be reduced still further by stripping with dry gas or applying a vacuum. The stripping medium, often sweet gas, is passed through the storage vessel to be heated in the spiral tube before the desorption of the water vapor in the distillation section is increased. A residual water content in the glycol of $< 0.3\,\%$ can be achieved [29]. The dew points attainable

for natural gas in equilibrium with a triethylene glycol – water mixture are given in Figure 10 as a function of contact temperature. The plants are self-controlled; the dehydration process is maintained by indirect control of the glycol circulation rate, the regeneration temperature, and the stripping gas rate [30].

Figure 10. Attainable dew points of natural gas as a function of the (gas) contact temperature with triethylene glycol – water solutions

Enrichment of hydrocarbons in the glycol can be limited by the use of oil skimmers. Degradation products resulting from entry of oxygen, thermal decomposition, or influx of acids from bore hole treatment render glycol corrosive. Corrosion control is usually carried out by the addition of inhibitors that increase the pH. The glycol is usually filtered through activated charcoal. The service life of glycol can be several years [31].

Further measures are necessary for dehydration of sour gas, as shown by the dashed lines in Figure 5. At the usual plant pressure of 10.0 MPa, glycol absorbs considerable amounts of hydrogen sulfide, in addition to water vapor. The former is released during regeneration of the glycol, thereby leading to corrosion and emission problems. High-pressure strippers are therefore installed. At a pressure slightly above that of the glycol absorber, hydrogen sulfide is removed from glycol by stripping with heated sweet gas. The sweet gas often originates from neighboring fields or plants. The strip gas, enriched with hydrogen sulfide (representing $< 2\,\%$ of the dehydration unit capacity), is recycled to the absorber. Glycol dehydration units are constructed of normal carbon steel.

In the final phase of gas production from a well, considerable amounts of salt-containing formation water are coproduced. During flashing and transportation of these laden liquids, gases are released, including hydrogen sulfide and benzene – toluene – xylene (BTX). Emissions can be minimized and risks reduced by additional stripping or by recompression of these flash gases.

Adsorptive Dehydration. In adsorptive dehydration the gas is brought in contact with molecular sieves, silica gel, or SORBEAD (i.e., Na_2O-containing SiO_2). Plants with only two adsorbers, working alternately, are possible. Dew points $< -70\,°C$ are attainable with adsorption plants. This is particularly necessary for cryogenic plants and liquid natural gas (LNG) plants, where traces of water and carbon dioxide can lead to blockage by ice formation.

For *regeneration*, ca. 5 % purge gas is drawn from the main gas flow and fed through the laden adsorber at plant pressure and 200 – 330 °C (Fig. 11). Removed water vapor from purging of the fixed bed is condensed so that the purge gas, which is at plant pressure, can be recycled. Regeneration by depressurization is seldom employed in natural gas treating.

Under the normal requirements of natural gas treating dehydration units of this type are economically less attractive than glycol and cryogenic dehydration plants described above. However, they are nevertheless employed when, in addition to simply removing water, adjustment to a specific hydrocarbon dew point is required, removal of hydrogen sulfide or carbon dioxide is necessary, or an extremely low dew point is required.

The adsorbent lifetime depends mainly on the amount of impurities (e.g., salt, inhibitors, sulfur compounds, and waxy hydrocarbons) that originate from well production. Conversion of sulfur compounds to hydrogen sulfide or carbonyl sulfide in the adsorber has been observed. Ad-

sorption plants are often used in offshore fields to minimize the need for scrubbing solvents.

2.3.4. Removal of Hydrocarbons

Recovery of hydrocarbons is mainly done for economic reasons. However, removal may also be necessary to avoid uncontrolled appearance of hydrocarbon condensates in long-distance pipelines and low-pressure distribution systems in cities [32, 33]. Such condensates in pipelines may produce liquid slugs, especially during varying loads, which lead to errors in downstream measuring and controlling devices. In addition, plastic pipelines or plastic components in meters are adversely affected. Furthermore, condensates impair leak detecting by use of odorants. Therefore, in addition to a water dew point, a hydrocarbon dew point is often specified. Thus, condensation of hydrocarbons is avoided at ground temperature and typical pressure ranges of the transportation system (10 – 0 MPa) [34].

Higher hydrocarbons strongly influence the dew point curves of natural gas and also determine the conditions under which retrograde condensation can occur (see Section 1.2). As an example, the dew point lines of an untreated and a treated natural gas are shown in Figure 12. The vapor pressure curve of pure methane is also shown.

Figure 12. Phase diagram for natural gas containing higher hydrocarbons and for pure methane
a) Dew point curve; b) Boiling point curve; c) Critical point; d) Cricondentherm point

The required hydrocarbon dew point cannot be attained with cryogenic processes. Industrially, adsorption plants with activated charcoal or SORBEAD are used, in which the higher hydrocarbons are removed and recovered preferentially at elevated regeneration temperatures and short cycle times (see Fig. 11). Presence of water causes problems and is usually removed first in upstream dehydration plants [32].

2.4. Removal of Carbon Dioxide and Sulfur Components

Removal of the sour gas components hydrogen sulfide and carbon dioxide is one of the most common aims of natural gas treating. Furthermore, other sulfur compounds (e.g., COS or mercaptans) are frequently present and must also be removed. The quality demands on purified gas and the anticipated type of processing or further use of the separated components are quite varied. As a result, a choice of many different processes is available [35].

2.4.1. Absorption Processes

The method with the broadest application is gas scrubbing. Here, the sour gas components are reversibly bound to a solvent by chemical or physical absorption. In the regeneration step the components are desorbed unchanged and the solvent is recycled to the scrubber.

2.4.1.1. Physical Absorption Process [35 – 37]

If *selective removal of sulfur compounds* is required for natural gases with a high content of sour components, physical absorption processes are preferred. In physical absorption, carbon dioxide and hydrogen sulfide are only physically dissolved in the solvent. The process is reversible: during regeneration under strongly reduced pressure, absorbed gaseous components are released unchanged from the solvent (→ Absorption, Chap. 4.1) (Fig. 13).

Important processes include the following: (1) the Purisol process, which operates with *N*-methylpyrrolidone (NMP); (2) the Selexol process, in which the solvent is a mixture of poly(ethylene glycol dimethyl ether)s; (3) the Sepasolv process, with poly(ethylene glycol methyl isopropyl ether); (4) the Fluor solvent process, with propylene carbonate; and (5) the cold methanol process (Rectisol). With the exception of the Rectisol process (which operates at −10 to −30 °C), all operate at ambient temperature and employ high-boiling organic solvents (Table 6). The absorption properties for carbon dioxide are similar; the selectivity of NMP for hydrogen sulfide is higher, which is often desirable.

Figure 13. Physical scrubbing with regeneration by depressurization and stripping
a) Absorber; b) Solvent recovery; c) Stripper; d) Recompressor

Physical scrubbing agents are usually anhydrous; thus both dehydration and removal of carbon dioxide and/or hydrogen sulfide can be carried out in a single step; the separate dehydration step usually required in chemical absorption process is superfluous. At a water content of ca. 3 – 5 % in the scrubbing agent (e.g., Selexol), it is also possible to regenerate without a strip gas compressor; the stripping agent is then the water vapor present.

To reduce losses and prevent condensation of the scrubbing agent in the pipeline, small post-treatment units are often installed (e.g., with glycol). Washers, activated carbon adsorbers, or refrigeration systems, are also possible. Because of the good solubility of higher hydrocarbons in these physical solvents, these processes also allow the recovery of LPG.

Amount of Scrubbing Agent. The circulating amount of scrubbing agent required is almost independent of the concentration of the components to be removed but does depend on pressure and raw gas throughput. *Loading* of the physical scrubbing agent increases with the partial pressure of the components to be removed: Thus, physical absorption is used advantageously at higher concentration of these components and higher process pressure. A large amount of coabsorbed methane can be released in the first de-

Table 6. Characteristic properties of physical solvents

* at −25 °C.

pressurization step by flashing (usually multistage flashing) and can be fed profitably into internal fuel-gas systems.

A high selectivity for hydrogen sulfide compared to carbon dioxide leads to process streams with high hydrogen sulfide concentration, which can be used in the Claus process. A certain residual amount of carbon dioxide in the treated gas may be desirable to adjust its calorific value to required specifications. To match quality specifications, physical scrubbing processes can be operated with variable selectivity by adjusting circulation of the solvent and temperature.

Physical scrubbing processes are noncorrosive, and regular carbon steel is generally used as construction material. Complete removal of carbonyl sulfide from the crude gas requires sophisticated equipment.

2.4.1.2. Chemical Absorption Processes [35, 38 – 40]

Alkanolamine scrubbing, known since 1930, is currently one of the most frequently used processes (→ Gas Production). Aqueous solutions of monoethanolamine (MEA), diethanolamine (DEA), diisopropylamine (DIPA), diglycolamine (DGA), and methyldiethanolamine (MDEA), in particular, are used as absorbents. The choice of solvent is determined by different factors.

Monoethanolamine allows a high final purity but requires a considerable amount of energy for regeneration, and absorption of carbonyl sulfide leads to degradation products that must be eliminated in a reclaimer (see Section 2.8). Selective removal of hydrogen sulfide is not possible. *Diglycolamine*, like MEA a primary amine, is suitable for the complete absorption of both hydrogen sulfide and carbon dioxide and can also be used for scrubbing of carbonyl sulfide and mercaptans. The secondary amines *DEA* and *DIPA* show a lower heat of reaction for absorption – desorption of sour gas components; as a result, they require less regeneration steam than MEA. At higher carbon dioxide levels, various degradation compounds are formed that cannot be regenerated, and require use of a reclaimer (see Section 2.8). A certain selectivity for hydrogen sulfide is possible, particularly with DIPA, because its reaction with carbon dioxide is slower. Tertiary amines such as *MDEA* have considerably better selectivity for hydrogen sulfide. The heat of reaction with MDEA is lower, degradation products are not formed with carbonyl sulfide and carbon dioxide, and only a few corrosion problems arise. If gases at low pressure are purified, the normal pipeline specification for hydrogen sulfide is not attained. Comparative data for characterization of various alkanolamines are presented in Table 7.

Addition of *corrosion inhibitors* and special chemically active components leads to advanced processes that allow higher alkanolamine concentration and higher loading, for example, or better selectivity for hydrogen sulfide and, therefore, lower circulation rates. A lower corrosion tendency and a reduction of energy required for regeneration can thereby be obtained. Examples are the Amine Guard, Econamine, activated MDEA (BASF), Gas/Spec, and Ucarsol processes [41, 42]. Selectivity can be increased, and further savings in energy can be obtained by the use of sterically hindered amines (Flexsorb, Ucarsol Innovator Solvent 111). The energy consumption for the hydrogen sulfide/carbon dioxide or carbon dioxide scrubbing system is also lower with these amines [43, 44].

Table 7. Comparison of chemical solvents

Absorbent	Heat of reaction, kJ/kg		Relative CO_2 absorption,	Capacity *	
	H_2S	CO_2	%	H_2S	CO_2
MEA	1905	1920	100	0.07	0.50
DEA	1190	1510	40	0.09	0.32
DIPA	1140	2180	20		
MDEA	1050	1420	10	0.10	0.12

* Moles of sour gas per mole of amine for solutions with 1.3 mol of amine per kilogram water.

Activated and inhibited *potassium carbonate* solution (Benfield, Catacarb) is widely applied for purification of natural gas (→ Gas Production) [45]. The process can in principle be used to remove carbon dioxide, hydrogen sulfide, carbonyl sulfide, and carbon disulfide. However, it is used mostly in treating gases with high carbon dioxide content. The steam requirement for regeneration can also be reduced by addition of hindered amines.

2.4.1.3. Physical – Chemical Absorption Processes

The advantages of chemical absorption (e.g., removal of COS, low coabsorption of methane) are combined with those of physically effective organic solvents (e.g., high loading at high partial pressure). As amines, DIPA and MDEA are preferentially employed. The physical absorbents are high-boiling solvents (e.g., Sulfolan or Selexol). In addition, 5 – 30 % water is present. The Sulfinol process has found widespread use [46, 47] and has proved useful in the United States, Canada, and the Federal Republic of Germany for simultaneous removal of hydrogen sulfide, carbon dioxide and organic sulfur compounds. However, the coabsorption of hydrocarbons is also increased by a physical solvent, so that an intermediate flash step with reabsorber for the recovery of sulfur-free fuel gas (shown as a dashed line in Fig. 14) is indispensable. *Selective* hydrogen sulfide scrubbing can be attained with this process by proper choice of the amine.

Other physical–chemical absorption processes include Selefining, Flexsorb PS [44], and Amisol. With the Amisol process a mixture of methanol and alkanolamines or aliphatic alkylamines is used [48]. Like in all chemical scrubbing processes, the gas is saturated with water vapor in the absorption step, making a downstream dehydration unit necessary.

Selection Criteria for Absorption Processes [35, 38, 40, 49]. Selection of the best suited process is essentially determined by the pressure and composition of the raw natural gas, the trace components, and the desired quality of marketable natural gas and separated sour gas components. Investment and operating costs are also important. The design of the absorber and the amount of solvent required are determined by the absorption behavior of the least soluble compound to be removed. Of the investment cost, 50 – 70 % are directly related to the required amount of scrubbing agent in circulation. In contrast, operating costs are determined to about 70 % by the energy requirements for regeneration and recirculation of the scrubbing agent. In view of the many parameters to be considered, a simple selection of a process by means of a diagram or a table is not possible. Only a few factors can be mentioned here.

Raw Gas Composition. Physical absorbents are generally not used for the purification of natural gas that contains higher hydrocarbons. The solubility of butane, for example, in most solvents is similar to that of hydrogen sulfide. Selective removal of the latter, therefore, is not possible. Hydrocarbon solubility in aqueous chemical scrubbing agents is low. Unfortunately, some chemical absorbents react with gas components (e.g., COS, CO_2, and CS_2) to form corrosive products, whereas physical solvents remain unchanged.

Gas Throughput. Physical scrubbing systems are in general more complex and, therefore, require higher investment. For this reason, chemical scrubbers are often more economical for small gas streams if no side reactions with the chemical absorbent occur. For large plants,

Figure 14. Schematic of physical-chemical scrubbing with hot regeneration
a) Absorber; b) Air cooler; c) Regenerator; d) Air condenser; e) Intermediate flash stage with reabsorber; f) Reboiler; g) Phase separator; h) Expansion turbine

the low operating costs of physical absorption processes outweigh the higher investment costs.

Pressure. In *chemical absorption processes* the capacity of the solvent is determined by reaction of the sour gas components with the active solvent component; i.e., saturation is reached at relatively low pressure. The circulation rate is then proportional to the quantity of the components to be removed and thus also to the total pressure. For *physical scrubbing agents*, loading increases with pressure, and the circulation rate is inversely proportional to the total pressure.

Claus Gas. In most cases, the sour gas removed is fed to a Claus plant for recovery of elemental sulfur (→ Sulfur). For this purpose, the gas should have as high a content of hydrogen sulfide and as low a content of hydrocarbons as possible. If the gas to be purified contains a high level of carbon dioxide in addition to hydrogen sulfide, a selective absorption process is preferable. This requirement is better met by physical than chemical processes. If strip gas is used for regeneration, the hydrocarbon content of the Claus gas should be lowered by intermediate flashing stages and recompression.

Sales Gas. When hydrogen sulfide and carbon dioxide must be simultaneously and almost entirely removed, chemical or physical – chemical scrubbing processes can be attractive. The presence of organic sulfur compounds excludes some solvents. If only partial removal of carbon dioxide is required, selective amine absorption processes are used at low pressure, and physical processes are preferred at high pressure.

Special solvent properties such as vapor pressure, viscosity, toxicity, heat of absorption – desorption, and corrosion behavior must be considered, along with foaming tendency, water-absorbing capacity, pricing, and environmental impact. The decomposition products that must be disposed of can often be reduced by a reclaim and recovery unit.

2.4.2. Liquid Oxidation Processes

The conventional absorptive removal and separate processing of hydrogen sulfide is often too expensive, particularly when the gas stream to be treated is relatively small, the hydrogen sulfide content is low, or the pressure is low. In this case selective liquid oxidation processes can be used [50].

The following steps are generally involved in this process:

Absorption of hydrogen sulfide in alkaline solution
Oxidation of dissolved hydrogen sulfide ions to elemental sulfur with simultaneous reduction of a chemical oxygen carrier or microoganisms

Figure 15. Schematic of a liquid oxidation process
a) Absorber; b) Oxidizer; c) Settling tank; d) Centrifuge; e) Recirculating pump; f) Air blower; g) Chemical additive pump; h) Sulfur slurry pump; i) Sulfur melter

Reoxidation of the active component with air, in special processes with the aid of bacteria
Separation of elemental sulfur by filtration, centrifugation, flotation, or sedimentation and, if necessary, further purification.

The processes are differentiated from each other only by the specific redox system employed. A flow sheet is shown in Figure 15. The sour gas to be purified is brought in contact with the absorption solution in a venturi scrubber or an absorption column. The liquid, which may now contain elemental sulfur in colloidal form, is then treated with air to complete the formation of elemental sulfur and to reoxidize the reduced oxygen carrier which is then recycled to the absorption step. The sulfur sludge is collected and treated further.

The following processes are used:

1) *Stretford, Sulfolin, Unisulf*
Vanadates are employed for oxidation of the absorbed hydrogen sulfide. Organic oxygen carriers (e.g., anthraquinonedisulfonic acids) are required to reoxidize the vanadium compounds. Optimized formulations suppress side reactions (e.g., formation of sulfate and thiosulfate) and lower the consumption of chemicals.

2) *Takahax, Hiperion*
For these processes, naphthoquinonesulfonates or chelates are used as oxidizing agents. Some environmental problems associated with the use of vanadates can thus be avoided. In both groups of processes, hydrogen sulfide is absorbed very selectively; they are also suitable for gases with a high carbon dioxide content.

3) *Lo-Cat, SulFerox, Sulfint, Bio-SR*
After absorption in a solution of $NaHCO_3$ – Na_2CO_3, hydrogen sulfide is oxidized with iron(III) aminopolycarboxylic acid chelates. The resulting iron(II) chelates are reoxidized with air. Differences in composition of the solutions employed in individual processes influence the absorption capacity for hydrogen sulfide, the side reactions, the selectivity of absorption in the presence of carbon dioxide, and the ease of removal of sulfur particles. The Bio-SR process works at pH 2 and without chelates. Iron(II) sulfate is oxidized by *Thiobacillus Ferroxidans*[81]

4) *Sulfa-Check*
In this batchwise process, hydrogen sulfide is oxidized to elemental sulfur with a nitrite solution. The solution used and the sulfur-containing sludge must be disposed of.

5) *Thiopaq*
Thiopaq is a biological process for SO_2 reduction, employing absorption in caustic solution and a sulfur formation step by biological oxidation. It requires a sulfate bleed stream [82],[83]

2.4.3. Adsorption Processes

Adsorption processes for the removal of hydrogen sulfide and carbon dioxide are used in natural gas treatment predominantly when only small amounts of acidic components must be removed [51, 52].

Activated charcoal and zeolitic molecular sieves are used as adsorbents. Zeolites, in particular, are suitable for selective separations because of their ordered crystal lattice with extremely uniform pore size and their high adsorptive capacity. Typical equilibrium loading curves are shown in Figure 16.

Figure 16. Loading of molecular sieve 5A

Adsorption processes (→ Adsorption) are generally run continuously in such a way that the raw gas to be purified passes through at least one adsorber, while the other adsorber(s) undergo a regeneration cycle. Regeneration can be carried out by temperature swing, pressure swing, inert gas stripping, or a combination of these.

2.4.3.1. Adsorption of Carbon Dioxide

Molecular sieves are used widely for the purification of natural gas when it is used as feedstock for a cryogenic plant for production of liquefied gas. In these plants, even low levels of carbon dioxide cause problems because the gas freezes in the low-temperature unit and can lead to blockage. The simultaneous removal of traces of water by molecular sieves is also an advantage here. A gas quality of < 50 ppm of carbon dioxide and 1 ppm of water can be attained in this way.

The main elements of an adsorption plant with three towers based on the temperature swing process are shown in Figure 11. The first tower (a) is in the adsorption stage for purification of the raw gas; the second (b) is cooled with the treated gas which, after being heated, regenerates the adsorbent in the third tower (c). After completion of this adsorption – regeneration cycle the function of the three identical towers is changed by automatically controlled valves. The regeneration gas, which is enriched in carbon dioxide, can be used for heating. In large plants, however, the volume of regeneration gas may become so large that absorptive workup and recirculation should be considered.

2.4.3.2. Adsorption of Hydrogen Sulfide

Various adsorptive processes are available for the removal of hydrogen sulfide; these are differentiated by the type of binding to the adsorbent and the method of regeneration. *Activated charcoal, iron oxide*, and *zinc oxide* are generally used only for the removal of smaller amounts of hydrogen sulfide because of the limited regeneration capability of these adsorbents [53].

Molecular sieves display a high affinity for sulfur compounds. These materials can be selected to permit simultaneous dehydration and desulfurization without removal of carbon dioxide from the gas. Plants are in service which can purify gas containing 10 – 6000 ppm of hydrogen sulfide and 0.1 – 50 % carbon dioxide. The valuable but hydrogen sulfide-rich regeneration gas is usually treated further [54] and reused.

With special molecular sieves, hydrogen sulfide can be removed and, in the presence of carbon dioxide, converted to carbonyl sulfide:

$$H_2S + CO_2 \rightarrow COS + H_2O$$

For gas with low hydrogen sulfide content the permitted level of carbonyl sulfide in marketable natural gas can be exploited by this means. Re-

generation and further treatment of the hydrogen sulfide-containing desorption gas are then no longer necessary. A survey on adsorption processes is given in Table 8.

Table 8. Adsorption processes

Basic process	Examples	Product
Adsorption	adsorption from oxygen-free gases on active carbon or molecular sieves	H_2S rich gas
Adsorption and chemical reaction	chemical reaction with ZnO	ZnS
Adsorption and oxidation	regeneration by extraction or desorption	
Chemical reaction and oxidation	reaction of H_2S with iron to Fe_2S_3 regeneration by oxidation to Fe_2O_3 and elemental sulfur	S/Fe_2S_3
Adsorption, catalysis	oxidation of H_2S with O_2 to elemental sulfur under active carbon catalysis	S

2.5. Membrane Processes

Gas separation with membranes has developed into an economically interesting process in the last decade. Membranes can be used for almost all aspects of natural gas treating. The following are of particular interest:

Separation of carbon dioxide and methane
Removal of carbon dioxide and hydrogen sulfide
Dehydration
Recovery of higher hydrocarbons [55 – 57]

Poreless, dense polymer films are used for the separation of gas mixtures. Individual components of the gas dissolve in the polymer and move through it by diffusion. Material transport can be described by the following steps: absorption from the gas phase into the membrane matrix, diffusion through the membrane, and desorption out of the membrane into the gas phase. The general rule is that a larger available membrane surface area, thinner effective membrane separating layer, greater difference in partial pressures, higher membrane-specific flow rate of the components to be separated (permeation coefficient), and better selectivity for individual gases result in more complete separation of a mixture. A multitude of polymer membranes are connected in a module to reach as high a packing density as possible. Hollow fiber, spiral-wound, and envelope-type modules have become generally accepted. The principle of a two-step module plant for the treatment of sour natural gas is shown in Figure 17.

The most widespread membrane processes are those for the separation of carbon dioxide from natural gas. An overview of the membrane and module types used in this area is given in Table 9.

A large number of membrane plants are in service in the United States. They are used to reduce the carbon dioxide, hydrogen sulfide, and water content of natural gas directly at the well. Membrane separators are simple to operate and require no electrical energy, coolant, or chemicals. They function without moving parts and can be operated with a minimum of supervision and maintenance. The permeate containing the separated components can, depending on its composition, be used as low-calorific fuel gas employed in the recovery of sulfur, flared, or vented directly to the atmosphere.

The service life of membranes, the pressure difference required, and the loss of gas to the permeate must all be taken into consideration for process selection.

2.6. Cryogenic Natural Gas Separation

Cryogenic processes are always employed when very low-boiling components are to be separated because none of the processes thus far described is suitable. Examples are reduction of the nitrogen content in natural gas and recovery of helium. In these processes, distillation steps are combined in which the considerably different boiling ranges of the primary components methane, nitrogen, and helium can be employed for separation (see → Noble Gases).

2.7. Recovery of Sulfur

2.7.1. Claus Process

Sulfur is recovered directly in elemental form from treated natural gas only by liquid oxidation processes (see Section 2.4.2). With all other absorption and adsorption processes, the regeneration gas stream, containing mainly carbon dioxide and hydrogen sulfide is processed further,

Figure 17. Two-stage membrane process

predominantly by the Claus process. This process route to liquid sulfur is used widely in the natural gas industry [58].

High conversion rates of hydrogen sulfide are mandated worldwide by clean air regulations. Furthermore, the recovery of sulfur is also of economic interest. Liquid sulfur is stored and transported easily, and solid sulfur can be marketed in the form of slates, prills, and pills.

In the Claus process, hydrogen sulfide conversion occurs in a thermal and a catalytic step. The Claus reaction is based on the exothermic overall reaction

$$2\,H_2S + O_2 \rightarrow 2\,S + 2\,H_2O \qquad (1)$$

The first exothermic reaction step (Eq. 2) takes place in the combustion chamber at ca. 900 – 1100 °C:

$$2\,H_2S + 3\,O_2 \rightarrow 2\,SO_2 + 2\,H_2O \qquad (2)$$

Subsequently, sulfur dioxide reacts with additional hydrogen sulfide to form elemental sulfur (Eq. 3). This reaction occurs in the presence of catalyst in several consecutive steps at a stepwise reduction of temperature from 350 to 190 °C.

$$2\,H_2S + 2\,SO_2 \rightarrow 4\,S + 2\,H_2O \qquad (3)$$

Cooling of the process gas from the combustion chamber occurs in the waste-heat boiler, which is combined with a brick-lined combustion chamber. For each tonne of sulfur produced,

more than 2 t of steam is coproduced. Condensers are arranged between individual stages, in which the evaporation of water is used to cool the reaction gases as much as possible; the aim is to attain as high a degree of separation of elemental sulfur as possible.

Prior to the catalytic reaction, reheating of the gas occurs to the activation temperature of the catalyst (ca. 180 – 220 °C). Inactivation caused by condensation of sulfur must be excluded. In larger plants, both gas – gas heat exchangers and in-line burners are used. The latter must be run exactly and substoichiometrically because the Claus reaction is very sensitive to disturbances and catalysts are deactivated by reaction with oxygen. Attainable yields depend on the hydrogen sulfide content of the gas and the number of catalytic steps. The choice of catalyst and the heater – separator concept are also important. The pressure is predetermined: it is approximately the atmospheric regeneration pressure of the upstream gas scrubbing units. The pressure drop in sulfur recovery plants is 20 – 50 kPa.

In the combustion chamber and the waste-heat boiler, 50 – 70 % of the hydrogen sulfide is converted to elemental sulfur. The combustion chamber conditions and the construction of the burner—both multijet burners and single burners have been built for plants generating sulfur at up to 1500 t/d—influence the course of combustion and the formation of compounds that influence the process. Significant amounts of carbonyl sulfide, carbon disulfide, carbon monoxide, hydrogen, and sulfur trioxide are formed [59, 60].

Catalysts for the Claus process are generally based on aluminum oxide, which may also contain other metal oxides. Traces of sulfur trioxide, which may be formed by reaction of sulfur dioxide and traces of oxygen during start-up – shut-down, lead to rapid deactivation of the catalyst by formation of aluminum sulfate. Catalysts based on titanium dioxide are also available that are not sensitive to oxygen and hydrolyze more than 90 % of the COS – CS_2 formed in the combustion chamber, which would otherwise require additional measures in downstream off-gas purification plants [61, 62].

To achieve a high degree of sulfur recovery in a Claus plant, an exact amount of combustion air is required. This amount cannot be calculated precisely in advance because side reactions, such as the formation of hydrogen, carbon monoxide, carbon disulfide, and carbonyl sulfide, also have some effect on the optimal air quantity.

Continuously operating analytical devices for determination of hydrogen sulfide and sulfur dioxide concentration have been established. A sulfur recovery degree of 94 – 96 % can be attained with two catalytic reaction stages; with three reactors, > 97 % recovery can be achieved.

2.7.2. Tail-Gas Cleanup Processes

The sulfur recoveries attainable in Claus plants often do not meet the emission standards in force (exceptions are very small plants). Usually, various standards are set, depending on plant capacity. Mandated sulfur recoveries for plants in the Canadian province of Alberta are shown in Figure 18. Specific emission limits based on both the plant capacity and the hydrogen sulfide content of the sour gas are applied in the United States. In the Federal Republic of Germany a recovery of at least 99.5 % is demanded for all plants with a capacity of > 50 t/d [63 – 65].

Figure 18. Sulfur recovery requirements for Alberta sour gas plants (August 1988)

Posttreatment of Claus tail gases is therefore generally required. A series of tail-gas purification processes is available which also produce elemental sulfur. The most important industrially applied tail-gas treating processes are described below [41].

Processes Utilizing the Claus Reaction. In the first group the formation of sulfur according to the Claus reaction from hydrogen sulfide and sulfur dioxide is performed in an additional catalytic step. This step is operated at a temperature below the sulfur dew point, thereby shifting the

equilibrium in the direction of sulfur formation. In the so-called *dry-bed* processes the reaction and precipitation of sulfur occur over aluminum oxide catalysts. When the maximum sulfur load is reached the catalyst is regenerated with hot hydrogen sulfide-containing recycle gas, and then tail gas is passed to an already desorbed and cooled reactor. Sulfur recoveries of 98 – 99 % can be reached in this way. Established processes include the following: Sulfreen, CBA, MCRC, and Maxisulf.

In the *IFP Clauspool* process the reaction is carried out in a high-boiling solvent that contains a catalyst; the sulfur formed is drawn off as a liquid. Yields correspond to those of the dry processes.

Sulfur recoveries of 99 % can also be attained with the *Superclaus 99 process*, first introduced commercially in 1989. A conventional Claus plant is run with a substoichiometric amount of air, so that practically no sulfur dioxide appears in the tail gas. Unreacted hydrogen sulfide is converted to sulfur by reaction with air in a downstream reactor using a special iron – chromium catalyst with a small specific surface area [66, 67].

Processes with Catalytic Conversion to Hydrogen Sulfide. In the second group, all sulfur-containing components in the Claus tail gas are catalytically converted to hydrogen sulfide. Further treatment takes place after cooling and condensation of a large part of the water vapor [68]. The following treating processes exist:

1) Absorption processes with regeneration. The hydrogen sulfide removed is returned to the Claus plant. The Scot, Sulften, and BSR–MDEA processes (→ Sulfur) are representatives of this group. To reduce energy consumption, absorbents are being developed which show better selectivity for hydrogen sulfide and lower energy requirements for regeneration (Flexsorb, Ucarsol).
2) Liquid oxidation processes by which absorbed hydrogen sulfide is converted in solution directly to elemental sulfur (Stretford, Sulfolin, and Unisulf process, see Section 2.4.2). Sulfur of lower quality is produced than with the other methods.
3) Catalytic processes in which hydrogen sulfide is converted to sulfur in the gas phase by addition of air, oxygen, or sulfur dioxide. The sulfur is recovered by condensation. Representatives of this group are MODOP [69], Selectox, and Ultra (→ Sulfur).

All processes in this group can be designed so that sulfur recoveries of 99.5 % are attainable. With absorption processes, a recovery of > 99.7 % is possible.

Processes with Catalytic Oxidation to Sulfur Dioxide. This group encompasses processes in which all sulfur-containing components are oxidized to sulfur dioxide. After cooling, sulfur dioxide is removed by absorption. The sulfur dioxide-rich gas arising from regeneration of the laden solvent is recycled to the Claus plant. The Wellman – Lord and Solinox processes, in which a sulfur recovery of > 99.5 % can be achieved, is commercially important.

2.7.3. Incineration

With only a few exceptions, the off-gas from Claus plants or tail-gas cleanup plants must be fed to an incinerator in which the residual sulfur-containing components are oxidized to sulfur dioxide. For thermal incinerations 600 – 800 °C is necessary, whereas catalytic plants require only 300 – 350 °C. All these processes lead to an off-gas with < 10 mg/m^3 of hydrogen sulfide. If the off-gas to be treated contains other sulfur compounds such as carbonyl sulfide or carbon disulfide, then a value of 10 mg/m^3 can also be obtained in a thermal incineration plant, provided the temperature is sufficiently high. For the catalytic process in this case, however, up to 80 mg/m^3 of sulfur must be expected in the off-gas. In principle, energy recovery by waste-heat boilers or gas – gas heat exchangers is possible for both processes. Nevertheless, traces of sulfur trioxide can lead to condensation of sulfuric acid in the heat exchanger. To avoid corrosion, heat exchange must be limited which means that less energy can be saved [70].

2.8. Example of an Integrated Plant

A flow diagram of an operating plant for the purification, dehydration, and conditioning of two different raw natural gases is shown in Figure 19. The design capacity amounts to a maximum of

Table 10. Balance of a sour gas treating plant (nonselective chemical – physical scrubbing)

Quantity	Sour gas 600 000 m^3/h	Pure gas 473 200 m^3/h	Flash gas[a] 4500 m^3/h	Claus gas 127 000 m^3/h	Sulfur[b] 86.5 t/h

14×10^6 m^3/d for raw gas 1 and 5×10^6 m^3/d for raw gas 2. Characteristic data for the units processing raw gas are presented in Table 10.

Production of sulfur is set at 2100 t/d. The sour gases are predehydrated in the field (see Fig. 5) and are low in higher hydrocarbons. Treatment is thereby reduced to the removal of sulfur components and the adjustment of the inert-gas content. This special plant design has been chosen because of the following criteria [71]:

The high degree of carbonyl sulfide removal, which is necessary for underground storage of the pure gas, can be achieved with the chemical – physical Sulfinol scrubbing process. The latter is unselective but, depending on the ratio of hydrogen sulfide to carbon dioxide in the crude gas, may provide a sufficient Claus gas quality. The high energy consumption of solvent regeneration is also taken into account. The high-calorific pure gas can be stored in a nearby underground storage, but, after addition of nitrogen, can also be fed directly to the sales pipeline as low-calorific gas. The gas must be dehydrated because a water-containing scrubbing agent is used. The three-stage Claus plant attains a sulfur recovery of 97.5 %; the total recovery is increased to 99.8 % in a downstream tail-gas cleanup plant using the Scot process. After degassing, the sulfur produced is stored as a liquid and transported by rail. Sometimes the sulfur is solidified to prills or pellets outside the plant. Steam generated in a Claus plant is used in the reboiler for heating the Sulfinol solvent. Expansion turbines are employed for depressurization of the rich Sulfinol, which produce surplus electricity. In many cases the energy recovered from expansion, heat exchangers, and Claus waste-heat boilers is sufficient for regeneration and running the pumps. The total energy requirement of the sour gas treatment described here is ca. 3 % of the feed gas. One of the greatest consumers of energy is the tail gas purification plant.

Degradation of the DIPA content of the solvent to oxazolidone occurs because of the high carbon dioxide content of crude gas. The oxazolidone is regenerated to reusable scrubbing agent in a secondary plant. In another secondary plant a sulfur-dissolving agent, which prevents sulfur plugging of the wells (see Section 2.3.1), is regenerated for further use.

Lean raw gas 2, which contains a low level of hydrogen sulfide, is treated in a Purisol scrubber. Carbon dioxide remaining in the raw gas helps in adjusting the calorific value in the total pure gas stream from the Sulfinol unit. The flash gases are so low in hydrogen sulfide that they can be burned in a boiler.

Auxiliary Plants. Natural gas treating plants are connected to the public energy distribution network. Reliable auxiliary plants are required to guarantee a high level of availability and independence.

Steam Generation. Waste heat from the Claus process is used in the processing plant to drive process pumps and turbine-driven generators, and to heat solvents. The high-pressure steam generated is first expanded in turbines. The saturated low-pressure steam obtained can be used reboiling of the solvent at constant temperature. The reboiler steam pressure is 0.5 – 0.7 MPa and is adjusted to match the thermal stability of the solvent. Waste-heat boilers in the Claus plant operate at steam pressures of 1.6 – 4.0 MPa; the sulfur condensers at 0.1 – 0.6 MPa. By proper choice of driving equipment

a) Sour gas manifold; b) Town gas manifold; c) Disposal well
– · – · – Steam; – – – – Condensate

and steam pressure, energy requirements can be balanced so that only a little external energy is needed. Small amounts of blow-down streams must be continuously removed from boilers and condensers to avoid corrosion. These streams must be replenished by water from a treatment plant and a boiler feedwater degassing plant.

Electrical Power. Large compressors, circulating pumps, and blowers are often driven by steam turbines to achieve a better control of their speed. Frequently, the plant's own power station is only used for start-up and shutdown, whereby both steam- and gas turbine-driven generators are employed.

Inert Gas. Occasionally, purified natural gas must be mixed with inert natural gas to meet specified quality standards. When the admixing of air is not possible because of limitations of the oxygen content, inert gas plants are required. Inert gases produced from both catalytically purified flue gases and air separation are used. The dry gases are generally produced at low pressure

and brought to pipeline pressure (ca. 10 MPa) by multistage compressors. Inert gases are also employed for safe start-up and shutdown of plants and for regeneration of the Claus catalyst [72].

Tank Storage. Both higher hydrocarbons and sulfur are stored in tanks as liquids. They are transported further by road, rail, and frequently, pipeline. With special thermal insulation, liquid sulfur transportation through pipes of more than 8 km in length is possible without additional heating [73].

Wastewater. Natural gas treating plants produce little noxious wastewater. The boiler- and cooling tower blow-down water is fed to public sewage systems. Waste waters from piping and equipment cleaning are collected and treated in a reclaimer. Remaining residues are injected with the salt-containing formation water in separate disposal wells.

Gas Mixing. Different field qualities are mixed in the so-called raw gas manifold, so that the absorbers can be charged with gas of constant composition. Special separators minimize the entrainment of liquids and impurities that would damage the solvent or cause foaming. Pipelines from the field can be charged from the manifold with pigs for cleaning purposes. Mixing of different pure gases to adjust the Wobbe index and the net calorific value is possible in the pure gas manifold.

Reclaimer, Filter. Through side reactions, chemical scrubbing solvents in particular become enriched with degradation products, frequently of unknown nature. These substances are corrosive and may cause foam formation in the absorbers. Solvent quality is stabilized by removing a small side stream and addition of fresh solvent. This side stream is processed in a *reclaimer*, which is usually an auxiliary distillation plant. Purified absorbent can be reused in the process [74].

With physical scrubbing agents, removal of undesired substances (e.g., hydrocarbons) is frequently achieved by addition of water and phase separation. Mechanical filters are used in a side stream.

Special Construction Features. High partial pressures of carbon dioxide and hydrogen sulfide in a wet environment lead to serious corrosion. In particular, the stress corrosion cracking (SCC) caused by hydrogen sulfide corrodes high-strength steel from inside: atomic hydrogen can be formed by acid corrosion in connection with water, and can diffuse into the steel because of its small size of the atom. The hydrogen atoms recombine in the area of microcracks and local inhomogenities; the resulting pressure, which can reach 10^5 MPa, leads to cracks and blistering (hydrogen-induced cracking).

High-alloy hard steels are particularly susceptible; the necessary construction and testing regulations must be adhered to. Consequently, the carbon content of the steel is limited. Equipment and pipeline welding joints must be annealed. A hardness H_{RC} of < 22 must be maintained. Excessive stresses (particularly at plate edges) and thickness changes which are caused by the fabrication techniques must be avoided. Specially designed forged nozzles based on finite element analysis are customary [75].

3. Liquefaction

The principal reason for liquefying natural gas is a 600-fold reduction in volume that occurs with the vapor-to-liquid phase change. In its naturally occurring vapor state, natural gas is a bulky energy source, which is sometimes cumbersome to handle. Storage of the vapor requires huge underground caverns or large telescoping storage tanks. Transporting natural gas from production sources to points of consumption necessitates large pipeline networks. Thus, only overland or somewhat shorter undersea routes can be considered. Finally, natural gas at atmospheric pressure is too bulky to be considered as a fuel for transportation purposes; at the very least, it must be compressed.

Liquefaction of natural gas serves to overcome these obstacles, and permits transport over larger distances and more diverse application of liquefied natural gas (LNG) as an energy source. For example, LNG produced in the Middle East and throughout the Pacific Rim supplies ca. 10 % of Japan's primary energy consumption. Storage of LNG near urban areas permits peak demands for natural gas to be satisfied without building additional pipelines that would be underutilized most of the time.

Compressed natural gas is a feasible transportation fuel for truck and bus fleets. However, more recent aircraft and railroad applications

[87] require the higher energy density of LNG to be commercially viable.

3.1. Physical Properties of LNG

In the nomenclature of the energy industry, LNG is on the light end of the liquefied gas spectrum that also includes natural gas liquids (NGL, primarily ethane with some propane) and liquefied petroleum gas (LPG; → Liquefied Petroleum Gas, which consists mainly of propane with a significant proportion of butane). Common to each of these products is the lack of a standard set of physical properties. Nevertheless, certain characterizations of LNG are possible and useful.

Because methane is its primary component, the boiling point of LNG at atmospheric pressure is ca. −160 °C. Liquefied natural gas is odorless and colorless. Trace contaminants, especially mercury, can render LNG potentially corrosive if they are not removed to sufficiently low levels during the prepurification (see Chap. 2) and liquefaction processes. Liquefied natural gas is a commercial product, so the need to avoid solidification of trace contaminants is buttressed by rigid specifications for an environmentally acceptable fuel. Therefore, contaminants such as water vapor, carbon dioxide, and sulfur compounds, which may be found in vapor-phase natural gas, generally do not exist in LNG. Similarly, the relatively low boiling point of LNG limits the maximum concentration of pentane and heavier hydrocarbons that can exist in the liquid phase.

3.2. History

Early attempts to commercialize LNG failed. Barge transport between stockyards in Chicago, Illinois and gas fields in Louisiana did not employ adequately designed storage [88]. Similarly, a prototype peak-shaving storage tank in Cleveland, Ohio failed in 1944 because of poor material selection. The resultant spill from the tank vaporized, traveled through an adjacent sewer system, and caused a number of remote casualties upon ignition. These early setbacks, as well as the subsequent explosion of a poorly designed LNG tank undergoing repair on Staten Island, New York in 1973, did much to hinder the commercialization of LNG in the United States. Much of the early development centered around Europe and North Africa.

The first *baseload* LNG trade began in 1964 from Algeria to Canvey Island in England and to Le Havre in France. Subsequent projects were built in Libya and Algeria to supply LNG to Europe and its expanding pipeline grid. Japan became a purchaser of LNG in 1969, with the receipt of its first cargo from Kenai, Alaska. Since that time, Japan has become the preeminent buyer of LNG in the world. Major production facilities now also exist in Indonesia, Qatar, Abu Dhabi (United Arab Emirates), Brunei, Malaysia, Australia, Oman, Nigeria, Trinidad, and Egypt. As of 2005, more than 120 million metric tons per year of LNG is being produced, and facilities under construction will produce an additional 60 million metric tons per year.

Peak-shaving applications of LNG expanded rapidly in the late 1960s and throughout the 1970s in both Europe and North America. This growth mirrored the increased use of natural gas in urban areas and, in particular, the preponderant use of natural gas for heating. Virtually no growth of the peak-shaving business occurred in the 1980s because of a number of diverse factors, ranging from energy conservation and environmental siting restrictions to changes in governmental regulations.

Experiments in LNG *fueling of transportation vehicles* have been carried out for more than 20 years. Several driving forces exist for this work, including the environmental advantages of natural gas combustion compared to conventional fuels. However, no major infrastructure for LNG fueling exists to support the conversion of automobiles and trucks. Current development for railroad and marine vessels is, therefore, focusing on closed-loop applications in which the vehicle returns to the fueling station as part of its normal routing. Fishing vessels may also profit from the low temperature of LNG, which can be used to refrigerate the fish that are caught. Similarly, to best utilize LNG as a fuel for high-performance aircraft, the leading edges of the wings may have to be cooled with LNG to reduce skin-friction drag, while the LNG is being vaporized for use in the aircraft's engines.

3.3. Production

Because of the high critical pressure of methane, LNG must be produced commercially by refrigeration rather than pressurization. A number of processes have been commercialized for LNG production.

Common to all natural gas liquefaction processes is the need to pretreat the gas feed for removal of components that would freeze out (thus restricting the flow of the process), cause corrosion, or lead to pollution upon combustion of the revaporized LNG (see Chap. 2).

3.3.1. Baseload Liquefaction Processes (→ Refrigeration Technology,→ Cryogenic Technology)

Large-capacity or baseload liquefaction of natural gas is performed with emphasis on process efficiency. The scale of operations means that production with lower installed power capacity and lower fuel consumption is economically favored. Because the heat that must be removed from natural gas to cool it to −160 °C is eventually rejected to ambient air or water, rather elaborate systems have resulted.

Cascade Refrigeration Processes. The earliest liquefaction processes employed cascades of single-component refrigerants in series (→ Refrigeration Technology) (see Fig. 20). Each refrigerant is established as a separate closed-loop refrigerator that supplies refrigeration at discrete temperature levels. Typically, propane, ethylene, and methane are used to provide a wide, balanced range of refrigeration. After compression (a) three temperature levels for each of the three refrigerants form a nine-stage cascade. Each of these temperature levels corresponds to a preset pressure letdown (d) for evaporating the refrigerant in heat exchange with the natural gas feed and a separate refrigerant stream that requires cooling (e). In this fashion, heat is removed from the natural gas at successively lower temperatures; i.e., the refrigerant is boiled at successively lower pressure. Heat is rejected to ambient air or water via the warmest refrigerant, generally propane, and compressor aftercoolers (b). The methane refrigerant loop is open in that it is combined with the natural gas feed and after the final pressure letdown the liquid methane forms part of the LNG product. Cascade processes allowed use of single-component refrigerants at a time when thermodynamic correlations and thermophysical data bases were not as well developed as they are at present. In addition, the processes could be made very efficient (i.e., the amount of irreversibility could be reduced) by increasing both the number of refrigerants employed and the number of boiling stages for each refrigerant. This improvement in efficiency, however, had significant cost penalties. Each refrigerant requires its own compressor, compressor driver, vessels, and heat exchangers, together with attendant piping, insulation, and instrumentation. Each additional stage of boiling adds to the number of heat exchangers and vessels and to the number of sidestreams entering the compressor.

All-Mixed-Refrigerant Processes. The problems of complex layout, relatively high capital cost, and limited train capacities inherent in cascade processes were addressed by the mixed-refrigerant processes that succeeded them. As equipment and analytical capabilities advanced, the refrigerants could be combined in a single refrigeration loop (see Fig. 21). In such processes, a single refrigerant mixture of pentane, butane, propane, ethane, methane, and nitrogen, for example, is constituted to match the cooling curve of the natural gas to be liquefied; i.e., the temperature – enthalpy warming curve of the mixed refrigerant closely tracks the natural gas cooling curve in (g). This reduces the irreversibility of the process. The same refrigerant is then condensed, a part against air or water at (d) and the balance at lower temperature in heat exchange against itself in (f). In the latter case, incoming gaseous refrigerant is cooled and condensed at elevated pressure in countercurrent flow against evaporating liquid refrigerant fractions, each flashed (h) to a much lower pressure and, hence, temperature. The all-mixed-refrigerant process has performed well in a number of plants and represents a simplification compared to the cascade process. However, it is not thermodynamically efficient enough to be economical in the face of rising energy prices. To match the cooling curve of the natural gas feed over the wide range from the temperature of cooling water or ambient air down to the liquefaction temperature, compromises in the

mixed-refrigerant composition are necessary. The wide range of boiling points for the refrigerant components also means that some of the heavier components are compressed to higher pressures than actually required for their condensation to ensure condensation of the lighter, lower boiling components such as nitrogen and methane. Such a recompression penalty cannot be avoided without a certain degree of separation of the refrigerant components such as occurs in precooled mixed refrigerant processes.

Figure 22. Cooling curve for a propane precooled mixed-refrigerant liquefaction process
a) Cooling curve of natural gas; b) Propane cascade; c) Mixed refrigerant (stage 1); d) Mixed refrigerant (stage 2)

Precooled Mixed-Refrigerant Processes. In the early 1970s, a third generation of processes, precooled mixed-refrigerant processes, developed from direct combination of the other two. The most widely used process employs two separate refrigeration systems, a propane cascade refrigerant loop in series with a mixed-refrigerant cycle that incorporates propane, ethane, methane, and nitrogen as components [89] (Fig. 22 shows the cooling curves for this process). The *propane loop* precools the natural gas and serves as an intermediate refrigerant for heat rejection from the mixed-refrigerant section to cooling air or water. The propane section can be fabricated from lower cost carbon steel, whereas the lower temperature sections require aluminum or nickel steels. Thus breaking the cooling process at the propane stage is compatible with economical material selection. Finally, by reducing the range of cooling that must be achieved by the mixed refrigerant, its composition can be optimized and energy losses due to recompression significantly reduced.

The increase in worldwide demand for LNG has prompted an increase in the capacity of liquefaction trains in order to take advantage of the economies of scale. This is being achieved by improvements in the liquefaction process as well as increases in the equipment capacity. For the most widely used processes, capacity increases of refrigerant compressors, gas turbines, and cryogenic heat exchangers have led to train capacities of nominally 5 million metric tons per year.

For larger train capacities, a hybrid process cycle (known commercially as AP-X^{TM}) has been developed [90, 91]. In this process, a cycle similar to the precooled mixed-refrigerant process is used to precool and liquefy the LNG (see Fig. 23A). However, the liquefied LNG is subcooled in a nitrogen refrigeration closed-loop process cycle (Fig. 23B). Nitrogen gas is compressed, cooled to near ambient conditions with cooling water or ambient air, and then further cooled to cryogenic conditions by expansion to lower pressure. The gaseous nitrogen is then used to subcool LNG, after which it is returned to be recompressed, completing the refrigeration cycle. By employing the nitrogen refrigeration cycle to subcool the LNG, the mixed-refrigerant only has to cool the LNG to about −115 °C (versus −150 °C to °160 −C for the typical precooled mixed-refrigerant process). This allows for a larger production capacity without a substantial increase in equipment size.

Additional process schemes have been developed that fall in the category of precooled mixed-refrigerant processes. If ethane is added to the precooling refrigerant to form a *dual mixed-refrigerant* process, then the precooling temperature can be lowered in accordance with the operating conditions of the loop and the proportion of ethane added [92]. With this process the re-

Figure 23. AP-X^{TM} process cycle
A) Propane precooled mixed-refrigerant process; B) Nitrogen refrigeration closed-loop process

frigeration duty can be shifted between the two refrigeration loops – a capability that may be useful in the face of changing feed gas conditions or changing power availability. The latter can occur because of ambient temperature changes that affect the power output of gas turbine drivers. A binary precooling refrigerant is somewhat more complicated to operate because simple pressure control is no longer adequate, but it may be preferred in certain scenarios.

Another precooled process has been proposed for plants that employ gas turbine drivers in the mixed-refrigerant section. In this configuration, waste heat from the gas turbines is used to separate ammonia and water in an *ammonia absorption refrigerator* [93]. This system could provide precooling duty while eliminating the need for costly compressors and drivers. This system has not been employed in an operating facility.

3.3.2. Peak-Shaving Liquefaction Processes

Peaking-shaving LNG plants differ from baseload facilities in several significant aspects that affect plant design. Peak-shaving plants are much smaller, operate only seasonally, and are often located near the point at which the pressure in gas trunk lines is decreased and the lines branch into lower pressure local gas distribution systems. The design emphasis for peak shavers is thus on capital cost minimization rather than high thermodynamic efficiency. *All-mixed-refrigerant* liquefaction cycles have therefore been employed in a large proportion of peak-shaving facilities. If a local distribution pipeline is available at a pressure substantially below that of the main gas trunk line, *expander processes* can be utilized to take advantage of the pressure difference as shown in Figure 24. Several variations exist, but the principle of these plants is to expand the inlet gas nearly isentropically through a turbine, thus rapidly lowering the temperature and partially liquefying the gas. The liquid is sent to storage, and the residual gas is compressed in a compressor mechanically linked to, and driven by, the expander. This gas is then sent to the lower pressure pipeline for distribution outside the plant.

Figure 24. Schematic of an expander liquefaction process a) Turbine expander; b) Separator; c) Compressor

3.4. Storage

Storage tanks for LNG are an important part of both baseload and peak-shaving LNG facilities. In addition, they constitute the major portion of the investment in import receiving terminals. Because of the high cost of these units and their importance in the overall safety of LNG facilities, a great deal of attention has focused on LNG tank design.

One of the earliest efforts in tank design was directed at proper *material selection*. The Cleveland, Ohio tank failure in 1944 was attributable to the use of 3.5 % nickel steel which became embrittled at LNG temperature. Subsequent to this, large-scale programs have proved the suitability of 9 % nickel steel, stainless steels, and certain aluminum alloys (5000 series) for LNG tank fabrication. Designs with the latter have been somewhat limited in size, because the coefficient of thermal expansion for aluminum is approximately double that for steel; in large tanks, such thermal movement during cooldown could result in tank failure.

Tank designs have also evolved as more sophisticated safety analysis has been applied to LNG installations [94]. Early designs featured an internal cryogenic liquid tank enclosed by an outer tank that contained the insulation system for the inner one. In some designs the outer tank contained gaseous nitrogen and was, in turn, connected to a variable-volume or bladder tank, which compensated for changes in the nitrogen volume due to changes in ambient temperature while avoiding pressurization or depressurization of the outer tank. In other designs, the roof of the inner tank was not gastight but merely supported insulation, and the outer tank served as a natural gas holder (see Fig. 25). In both designs, the outer tanks were fabricated of carbon steel and surrounded by a low dike to contain any LNG spills.

Analytical studies indicated that the prime safety risk with an LNG spill is the formation of a large product vapor cloud that can drift, ignite, and cause widespread damage. Subsequent designs incorporated outer tank materials less prone to failure at cryogenic temperatures and taller dikes built closer to the tanks. These measures lead to less free surface for any LNG spill from a tank failure and therefore a lower feed rate to the ensuing vapor cloud.

Additional studies reviewed the consequence of an external impact, such as a crashing aircraft, leading to tank failure and the effect of a catastrophic inner tank failure on outer tank containment. These studies all focused on the need for much more secure outer containment. Resultant tank designs have double-integrity tankage; i.e., a liquid spill from a failure of the inner tank is contained by a second concentric tank that is structurally independent of the first [95]. The outer tanks have been built of reinforced concrete with a stainless steel liner. Finally, full-height earthen berms have been built to protect the tankage from external damage and to contain the postulated asymmetric loading on the outer tank resulting from catastrophic failure of the inner tank. Where the site is too small to permit full development of earthen berms, inground storage or additional reinforced concrete outer containment is employed.

3.5. Transportation

3.5.1. Peak Shaving

Peak-shaving LNG facilities typically vaporize LNG from storage and send it out via a local distribution network. In some installations, however, LNG is merely stored and vaporized for send-out. These satellite facilities receive LNG from other production sites, which is transported in over-the-road trailers. The trailers are similar to those employed in transporting liquid nitrogen and oxygen, and consist of an inner cryogenic vessel and an outer protective vessel of noncryogenic material. The space between vessels is typically filled with expanded perlite insulation and evacuated to subatmospheric pressure to further decrease heat in-leak.

Figure 25. Simplified cross-sectional drawing of single-integrity LNG storage tank
a) Suspended deck; b) Outer tank; c) Sidewall insulation; d) Inner tank; e) Load-bearing insulation; f) Foundations; g) Dike

3.5.2. Baseload

Baseload LNG facilities are linked to their corresponding receiving terminals by fleets of large oceangoing tankers. Modern tankers typically can hold 125 000 m^3 of LNG. Each tanker employs one of several containment systems, which can be divided into three principal types. One design employs *free-standing spherical tanks* supported on cylindrical skirts (see Fig. 26). Each tank is insulated and located between bulkheads in a separate section of the ship. These compartments are blanketed with inert nitrogen gas, which is sampled periodically to detect any LNG leakage.

Figure 26. Spherical ship tank
a) Weather cover; b) Tank; c) Insulation; d) Support skirt; e) Thermal break; f) Inner hull; g) Ballast tank; h) Outer hull

A second family of designs is the *membrane tank*. In ships using this type, the insulation and a secondary barrier are applied to the hull of the ship (Fig. 27). The insulation also transmits the load from the LNG cargo to the hull and its structure. A metallic membrane containment barrier is then installed over the surface of the insulation. The membrane may consist of Invar (highly alloyed steel with an extremely low coefficient of thermal expansion) or of a "waffle" structure (made of nickel steel), where the cross section of the waffle allows two-dimensional thermal movement while maintaining intimate contact with the load-bearing insulation. Membrane tanks are also compartmentalized and enable more efficient storage use of the hull volume. This manifests itself in a flattop deck and a lower center of gravity, whereas spherical tanks extend up through the deck and require domed covers.

Figure 27. Membrane ship tank
a) Membrane liner; b) Insulation; c) Inner hull; d) Ballast tank; e) Outer hull

A third type of LNG tanker employs *free-standing prismatic* tanks. This design seeks to combine efficient use of hull space with the structural independence of a self-supporting structure. A number of earlier ships were built with this design type, but it is relatively expensive and, with the exception of two smaller ships for the Alaska – Japan trade, is not employed in newer tankers.

3.6. Safety Aspects

Liquefied natural gas may be viewed as a creation of the modern era, and as such, it has been subjected to more thorough scrutiny than traditional fuels such as gasoline and fuel oil. The hazards associated with LNG are that it is a low-temperature fluid, is flammable, and can create vapor clouds dense enough to cause asphyxiation. Because none of these is a problem when LNG is contained in properly designed storage tanks or piping and equipment, safety studies have generally focused on LNG spills. In LNG facilities, extensive safety systems exist to detect gas leaks, to detect and counter fires, and to detect smoke. Spill prevention and containment are implicit in the design of plant facilities, particularly of storage tanks because they contain the greatest quantity of LNG.

If an LNG spill is ignited soon after it occurs, a pool fire results. This fire is certainly a problem, but it is contained in a facility staffed and equipped to deal with such emergencies. A greater concern is that the same spill may be given sufficient time to evaporate and form a vapor cloud that can travel for some distance before ignition. A number of variables such as the nature of the surface underneath the spill, the wind velocity, and the presence of obstructions to the cloud act to shape and direct it [96]. Mechanically, the cloud is formed as LNG boils from the surface of the spill [97]. The evolving vapors are much colder than air and initially form a dense, low-lying cloud. As the cloud mixes with air and is warmed by its surroundings, it begins to rise. Wind serves to add a horizontal component to the cloud's motion. As air mixes with the natural gas, the mixture becomes flammable (i.e., local compositions are between the lower and upper flammability limits of LNG). The flammability limits vary with LNG composition, particularly the proportion of propane. This cloud is then potentially hazardous to areas beyond the battery limits of the LNG facility.

A number of large-scale tests have demonstrated certain characteristics of LNG vapor cloud fires. These fires are deflagrations-rapid combustions in which the flame front that moves through the cloud is preceded by a weak, decoupled shock wave [98]. An accompanying radiation hazard exists, but not the pressure damage of a shock wave that occurs when mixtures of other hydrocarbons and air are detonated.

4. Transmission, Storage, and Distribution

More than 50 % of world gas reserves are located in remote areas. For example, part of the gas used in Western Europe is produced in the harsh permafrost environment of Siberia or in the North Sea.

In most cases, producers ship the gas from the fields to the borders of the countries in which it is used. Importers buy the gas at these points under long-term contracts and resell the fuel to local utilities as well as to industrial users and power stations connected directly to the transmission system. Residential and commercial consumers are normally served by the local distribution companies. The European natural gas transmission system is shown in Figure 28.

Natural gas is used chiefly for heating. Therefore, gas demand varies substantially between winter and summer, weekdays and week-ends, or day and night. The ratio between summer and winter loads in Europe is between 1 : 5 and 1 : 10. Production, transmission, storage, and distribution facilities must be designed and sized to handle these load variations.

Of the gas traded across international borders, 75 % is shipped by pipelines, and 25 % is carried by LNG tankers.

Gas field development and the construction of transportation systems from distant areas of production to gas-importing nations are highly capital-intensive projects. Thus, the load factors at which gas is imported are nearly always very high. For load equalization, gas is stored in underground storage facilities during the off-peak

Figure 28. European natural gas transmission system

season and produced from storage during periods of peak demand in winter. Pipeline pressurization (line packing) in the transmission and distribution systems themselves, as well as peak-shaving installations, also help to handle load variations.

4.1. Transportation

4.1.1. Pipeline Transmission

Transportation of large gas volumes is best achieved by large-diameter pipelines operating at high pressure. Currently, the pipeline diameter may be up to 1400 mm and working pressure up to 8 MPa. Such pipelines carry gas at a flow rate of 2×10^6 m^3/h (STP) over a distance of ca. 1000 km. This capacity is insufficient, however, to ship gas from distant fields to markets. Compressor stations must therefore be built to increase the pressure of the gas. Gas compressors are normally driven by turbines or engines fueled by their own pipeline gas for reliability and lower cost. The number of compressors required for a given carrying capacity depends on the distance over which the gas must be shipped and on the compression ratio, which is given by

$$\pi = \frac{p_o}{p_i} \tag{1}$$

where p_o is the maximum compressor outlet pressure (bar) and p_i the minimum compressor inlet pressure (bar).

As the compression ratio increases, the number of compressors needed to operate a gas transmission line decreases. Hence, transmission engineers must seek to optimize capital outlay and follow-up operating expenses for pipelines and compressor stations.

For large-diameter pipelines, the optimum compression ratio is generally relatively low; it is between $\pi = 1.25$ and $\pi = 1.4$ [99]. Offshore pipelines are currently built with diameters up to 1000 mm. Pipelines from the North Sea to continental Europe are 1000-mm-diameter lines that are laid at a water depth of 150 m; Italy and North Africa are connected by 500-mm lines that cross 600-m-deep water. The very high working pressures at which offshore lines can be operated partly make up for the loss in capacity due to the smaller diameters. If necessary, pipeline bundles are laid [100].

Offshore compressor stations are extremely costly structures because they must be built on platforms. For this reason, the optimum compression ratio of offshore pipelines is higher than that of onshore pipelines. Depending on flow, it may be as high as $\pi = 4$.

4.1.2. LNG Transportation

Although the energy input required for liquefaction of natural gas is substantial (see Section 3.3), the volume advantage makes liquefaction economically viable. Cryogenic LNG is shipped by LNG tankers at atmospheric pressure. The cargo tanks are insulated to minimize evaporation. Nevertheless, the boil-off rate is between 0.2 and 0.25 % of the cargo per day. The gas that evaporates is used to fuel the ships engine. Reliquefaction is presently not viable.

The transportation of LNG is often the only way of bringing gas from distant gas-producing countries to market outlets. Any cost comparison between LNG transportation and pipeline transmission must, of course, be geared to the circumstances of the project. Generally speaking, an LNG chain is the only answer if pipeline transmission is not feasible for technical or other reasons or if the distance is sufficiently long. The cost of LNG transportation is lower than that of offshore pipeline transmission even for distances of several hundred kilometers, whereas onshore transmission is nearly always less expensive than LNG transportation unless the distance is extremely long [99, 101 – 103]. A comparison of costs of LNG transportation and pipeline transmission is given in Figure 29.

Figure 29. Cost of LNG transportation and cost of pipeline transmission as a function of transportation distance
a) Offshore pipeline (900-mm diameter); b) LNG transportation with liquefaction onshore (125 800 m^3); c) Onshore pipeline (1000-mm diameter)

4.1.3. Gas Transmission Pipeline Design

Pipelines for gas transmission must be designed so that, under peak load conditions, gas is allowed to flow from the point of delivery at the inlet of the system to the outlet of the system at a pressure between the maximum and minimum allowable operating pressure. Generally, pipeline capacity is somewhat lower in summer than in winter because of the following reason: The atmospheric temperature increases soil temperature and hence gas temperatures, and power output from the compressor engine decreases because of the higher temperature of the intake air.

According to Darcy and Weisbach, the pressure drop in a gas transmission pipeline is given by the following equation:

$$p_1^2 - p_2^2 = f \cdot \frac{16}{\pi^2} \cdot \frac{l}{d^5} \cdot \varrho_n \cdot q_n^2 \cdot \frac{T}{T_n} \cdot p_n \cdot K \qquad (2)$$

where p_1 and p_2 are absolute pressures (Pa); p_n is the normal pressure, 1.01325×10^5 Pa; $p_1^2 - p_2^2$ represents the pressure drop (Pa^2); T is the absolute temperature (K); T_n the normal temperature, 273.15 K; ϱ_n the gas density under normal conditions (kg/m^3); f the pipe friction factor; q_n the flow rate under normal conditions (m^3/s); l the length of the pipeline (m); d the diameter of the pipeline (m); K the gas flow deviation coefficient; and subscript 1 denotes the pipeline inlet and subscript 2 the pipeline outlet.

Equation (2) is usually transformed into the following equation in which the pressure is ex-

pressed in bar and the flow rate in cubic meters per hour:

$$p_1^2 - p_2^2 = 4.6401 \cdot 10^{-15} \cdot f \cdot \frac{l}{d^5} \cdot Q_n^2 \cdot \varrho_n \cdot T \cdot K \quad (3)$$

where Q_n is the hourly flow rate under normal conditions (m^3/h); p_1 the absolute pressure at the pipeline inlet (bar); and p_2 the absolute pressure at pipeline outlet (bar).

Equation (3) may be rewritten using the following terms

$$p_1^2 - p_2^2 = K \cdot c \cdot Q_n^2 \quad (4)$$

where

$$c = 4.6401 \cdot 10^{-15} \cdot f \cdot \frac{l}{d^5} \cdot \varrho_n \cdot T \quad (5)$$

$$c\ (\mathrm{bar}^2 \mathrm{h}^2 \mathrm{m}^{-6}) \quad (5)$$

According to NIKURADSE, the pipe friction factor f for *turbulent flow* and rough-surface pipes is given by [104].

$$f = \frac{1}{\left(2 \cdot \log \frac{d}{k} + 1.14\right)^2} \quad (6)$$

According to the Colebrook equation, the following applies to the friction factor in the transition regime between a hydraulically smooth and a hydraulically rough pipe surface:

$$\frac{1}{\sqrt{f}} = -2 \cdot \log \left(\frac{2.52}{\mathrm{Re} \cdot \sqrt{f}} + \frac{k}{3.71 \cdot d} \right) \quad (7)$$

where k is the surface roughness factor.

The *limit* between hydraulic roughness and the transition regime is given by

$$f_1 = \left(\frac{200}{\mathrm{Re}} \cdot \frac{d}{k} \right)^2 \quad (8)$$

where the Reynolds number *Re* can be calculated by using the following Equation:

$$\mathrm{Re} = 353.678 \frac{Q_n^2 \cdot \varrho_n}{d \cdot \eta} \quad (9)$$

where η is the dynamic viscosity of the fluid (10^6 P a · s).

If the pipe friction factor is f_1, then the flow is in the transition regime.

For the design of new lined large-diameter pipelines, the pipe roughness factor k (in mm) is used in flow calculations:

Hydraulically rough regime (Nikuradse) 0.012 mm

Transition regime (Colebrook) 0.006 – 0.008 mm

The gas flow deviation factor K describing the real-gas behavior of natural gases is another important term in flow equations. For most natural gases, K may be approximated by

$$K = K\ (p_m, T_m) \quad (10)$$

$$p_m = \frac{2}{3} \cdot \frac{p_1^3 - p_2^3}{p_1^2 - p_2^2} \quad (10)$$

4.1.4. Increase in Capacity

If the capacity of an existing pipeline must be increased, (1) new compressor stations can be installed or (2) pipeline sections can be looped.

Installation of New Compressor Stations. The increase in capacity that can be achieved by the installation of compressor stations is given by

$$\frac{Q_n}{Q_0} = \sqrt{n+1} \cdot 100\% \quad (11)$$

where Q_n is the capacity of the system with compressor stations (m^3/h); Q_0 is the carrying capacity without compressor stations (m^3/h) and n is the number of compressor stations.

To maximize the increase in carrying capacity achieved by the installation of compressor stations, the compressor station sites must be optimized. The optimum site depends on whether flow is constant throughout the pipeline system or varies because of offtakes between the inlet and the outlet of the system (see Table 11) [105].

Looping of Pipeline Sections. The increase in capacity due to the installation of compressor stations increases the system cost in steps [106]. For this reason, additional compressor horsepower is not a cost-efficient method of increasing capacity for all additional capacity requirements. Alternatively, pipeline sections may be looped to obtain exactly the additional capacity that is needed. The increase in capacity achieved by a loop line of the same diameter as the main line is given by the following formula (if no gas is taken off between the inlet and the outlet of the pipeline system):

$$\frac{Q_L}{Q_0} = \frac{1}{\sqrt{1 - \frac{3}{4} \cdot \frac{L}{L_1}}} \cdot 100\% \quad (12)$$

Table 11. Optimum compressor station sites

Number of compressor stations	Site, % of total length		
	Pipeline without offtake	Pipeline with offtake	Maximal transport capacity, %
0			100
1	50	21	141
2	33 / 67	13 / 31	173
3	25 / 50 / 75	9 / 21 / 38	200
4	20 / 40 / 60 / 80	7 / 16 / 26 / 42	224

where Q_L is the capacity after addition of a loop line of length L_1 (m^3/h); Q_0 is the capacity without looping (m^3/h); L is the length of pipeline between inlet and outlet (m); and L_1 the length of the loop line (m). The length of the loop line required to provide a specified additional capacity depends critically on whether or not gas is tapped from the pipeline system between the inlet and the outlet points [105].

The increase in capacity as a function of loop line length is plotted in Figure 30. If a loop line of the same diameter is assumed, 75 % of the main line must be looped to increase capacity by 50 % if all gas flows from the inlet to the outlet of the transmission system. If gas is taken off regularly between the inlet and the outlet (as in the case of a regional line), only 40 % of the original pipeline has to be looped.

Figure 30. Increase in carrying capacity as a function of loop length

4.1.5. Transient Flow in Gas Transmission Systems

Flow rate and pressure in pipelines are a function not only of distance but also of time. Therefore, line packing effects play an important role. Simulation of transient flow, of course, produce different results than steady-state simulation. In a typical gas system, for instance, an hour of peak demand is usually preceded by a phase of low demand. As pressure increases when demand is low, a large gas volume is packed in the line when the demand peaks. During the period of peak load offtakes, the pressure in the line decreases because of the pressure drop resulting from the higher gas flow velocity through the line. Part of the gas packed in the line is therefore discharged from the system, covering peak demand.

Figure 31 shows the flows through a pipeline system into which gas is delivered at location 1 and from which gas is taken off at location 2 at different load factors. If the *flow rate* at the pipeline inlet (location 1) is constant (Fig. 31 A), inlet and outlet pressures will vary considerably and line packing will contribute substantially to covering peak load demand. As gas is normally delivered into a pipeline system at a continuous rate, the line will be repacked during periods of low demand, for example, during the night. If delivery into the pipeline system is at *constant pressure* (Fig. 31 B), the delivery rate will vary. However, the response at the point where gas is delivered into a pipeline system is always delayed with respect to the system behavior at the point where gas is taken off from the system; for this reason, delivery into the system and delivery from the system never coincide exactly.

Figure 31. Transient flow in gas transmission systems
A) Constant flow rate at pipeline inlet; B) Constant pressure at pipeline inlet

4.2. Storage

Gas storage facilities are integrated into the pipeline system to match the high load factor at which gas is produced and delivered by suppliers to the pattern of end-user demand, which varies between winter and summer, over the week, and from hour to hour.

4.2.1. Determination of Storage Requirements

Gas demand is influenced by many different physical and economic parameters. Because substantial quantities of gas are used for space heating, ambient temperature is the most critical one. Typical average daily deliveries Q_{d_i} in Northwestern Europe as a function of temperature are shown in Figure 32. Gas demand increases as a linear function of temperature decrease and is constant above a certain limit temperature. The correlation is represented by the following equation:

$$Q_{d_i} = Q_{d_g} + m\,(t_l - t_i) \tag{13}$$

where Q_{d_i} is the daily gas demand at the daily average temperature t_i (kW · h/d); Q_{d_g} the daily baseload gas demand (kW · h/d); t_l the limit temperature for space heating (°C); t_i the average temperature on a given day (°C); and m the increase in deliveries per °C decrease in temperature (kW · h d^{-1} °C^{-1}). This equation allows sufficiently accurate predictions of daily gas offtakes [100].

Figure 32. Daily average delivery as a function of temperature
10 m (slope) = increase in delivery per degree temperature decrease

Transmission, storage, and distribution facilities must, of course, be sized for the design day peak load on the system, determined by Equation (13). The ratio between system capacity speci-

fied for peak load conditions and capacity utilization is a crucial commercial and economic factor. Utilization time or system load is expressed differently in various countries.

In *Central Europe*, the concept of utilization time expressed in annual utilization hours or annual utilization days is frequently employed. *Utilization time* is given by Equations (14) and (15):

$$\text{Utilization hours per year} = \frac{\text{Annual gas volume}}{\text{Peak hourly volume}} \tag{14}$$

$$\text{Utilization days per year} = \frac{\text{Annual gas volume}}{\text{Peak daily volume}} \tag{15}$$

In the United States and the United Kingdom, the *load factor* expresses the same relationship. It correlates with the quantities given in Equations (14) and (15) as follows:

$$\text{Load factor} = \frac{\text{Annual volume}}{8760 \times \text{Peak hourly flow rate}}$$

$$\text{Load factor} = \frac{\text{Annual utilization hours}}{8760} \tag{16}$$

Figure 33. Daily load curve showing gas delivered from storage and gas added to storage

Irrespective of the actual load of the system, transmission, storage, and distribution facilities must be designed for adequate gas supplies regardless of ambient temperature or other conditions. With regard to storage facilities, gas deliveries from storage must at all times be sufficient to satisfy any demand in excess of gas supplies from gas fields into the transmission system. The volume of gas that is stored must be adequate to maintain this delivery throughout the period for which demand exceeds field supply. The necessary storage capacity is thus determined by the difference between the field supply load pattern and the demand load pattern, as well as by ambient temperature during the period in which supply is lower than demand. The volume of gas needed to satisfy peak demand must be stored from excess field supplies during off-peak periods. A typical daily load curve for a period of one year (for Northwestern Europe) is shown in Figure 33.

4.2.2. Storage Systems

Different systems are used by the gas industry to store gas during off-peak periods and to deliver gas from storage for peaking service. Various storage systems serve different peaking needs (see Table 12). The storage of gas in *low-pressure* containers has decreased substantially in importance because the quantity of gas stored in such a facility is insufficient.

Storage pipe arrays or *spherical gas tanks* in which gas is stored at high pressure provide peaking service for diurnal swings and short peaks within a week. Spherical gas tanks operate between 0.6 and 1.6 MPa and can have a diameter as large as 30 m. Pipes used for storage may hold gas at a pressure up to 8 MPa.

Line packing in *high-pressure* gas transmission pipelines is a method of handling diurnal peaks. For line packing, the pipeline must have a large diameter and must be designed for high working pressure. Line packing is feasible only if at least temporary spare capacity is available in the system. Normally, the transmission system design engineer plans a line packing capacity approximately eight times the difference between the hourly delivery rate and the peak hourly sendout into the system. This capacity corresponds to ca. 6 – 7 % of daily sendout.

Any demand peaks not provided for at the regional or the local level must be handled at the supraregional level. The quantities of gas that must be stored for seasonal peak shaving are substantial, and large underground storage facilities are practically the only system that will hold sufficiently large volumes of gas. Figure 34 shows the storage capacity that must be created to handle seasonal space heating load peaks as a function of supply load factor.

Table 12. Suitability of various storage systems for different peak needs

	Peaks			
	Daily	Weekly	Seasonal	System operator
Low-pressure container	×			local distribution companies
High-pressure container	×	×		
Line packing	×	limited		regional transmission companies
Cavern, fields	limited	×	×	supraregional transmission companies

Figure 34. Storage capacity required for seasonal peak shaving as a function of the supply pattern

Gas is stored below ground in appropriate rock formations (see Fig. 35). Suitable formations for underground storage of gas include porous or fissured rock as well as caverns mined in salt rock, for example. These formations must be covered with impermeable caprock to prevent gas from escaping.

The following types of underground storage facility exist:

1) depleted gas fields, oil fields, and aquifer storage facilities (porous rock storage);
2) salt cavern storage facilities; and
3) mined cavern storage facilities (only of minor importance).

Underground storage facilities hold both working gas and cushion gas. *Working gas* is the gas that may be produced from storage for peak-shaving operations.

Cushion gas, sometimes referred to as base gas, is the gas required to ensure sufficient reservoir pressure for recovery of the working gas. It provides the pressure needed to cycle the normal working storage volume.

Porous Rock Storage. Gas can be stored below ground in rock pores. The rock should have sufficient porosity and permeability, and the storage horizon (which must be at sufficient depth) should be covered by tight caprock and be a structure that entraps gas injected into the rock. Structures used for porous rock storage include depleted oil and gas fields as well as aquifer structures. Development of a gas storage facility in a *depleted gas field* does not pose a major risk because data on rock properties and information on the tightness of the caprock are available. The working gas capacity, the maximum reservoir pressure, and the delivery rates as a function of reservoir pressure are known from production history. For the storage of gas in *depleted oil fields*, gas – oil separators are needed; however, secondary oil production by gas injection often makes a depleted oil field a commercially attractive storage site [107].

In *aquifer storage* reservoirs, interstitial water in the pores is displaced by the gas injected at high pressure. Considerable geological and reservoir engineering effort is required to decide whether an aquifer structure is suitable for underground storage of gas: i.e., the structure of the potential storage horizon must be evaluated; the thickness, porosity, and permeability of the storage rock must be determined; and the thickness of the caprock must be verified.

Salt Cavern Storage. Gas may also be stored in caverns leached into salt rock. Unlike the volume of a natural storage rock reservoir, the volume of these cylinder-shaped caverns can be controlled within certain limitations. The diameter of such a cavern may be as large as 80 m and its height 400 m. The cavern volume can reach 500 000 m^3.

The capacity of cavern storage facilities can be adapted to increased storage needs by adding further caverns in a given formation as required. The cushion gas volume required for operation of a storage cavern is much lower than the base gas volume in a porous rock reservoir and may amount to only 20 % of total capacity. Storage caverns allow the production and injection of gas

Figure 35. Underground storage facilities for natural gas

at very high rates that are limited chiefly by the capacity of the above-ground installations.

In salt storage caverns, convergence can occur because cavern leaching operations and pressure cycling after commissioning produce strain in the rock. As a result, salt flows into the cavern, reducing its volume. Within limits, convergence may be controlled by retaining a minimum quantity of gas in the cavern [104, 107 – 109].

4.2.3. Optimized Storage Planning

As the load curve in Figure 33 shows, storage facilities produce gas for only relatively short periods of time. Depending on supply and demand load patterns, gas withdrawal is required for peak shaving on 80 – 150 days per year. If the ambient temperature rises, the withdrawal phase may be interrupted on days in which demand is lower than supply thereby allowing more gas to be injected into a partially depleted storage facility.

With *porous rock* storage facilities, production rates are limited by the resistance of the rock to gas flow to the wells. Depending on depth, reservoir pressure, and permeability, wells may produce gas at rates between 1000 and 70 000 m^3/h (STP). At *salt cavern* storage sites, the withdrawal rate is limited only by pressure loss in the tubing and the design of above-ground facilities. Storage caverns today are normally designed for production rates of up to 250 000 m^3/h (STP). However, because gas cools rapidly during depressurization, production at such a high rate is feasible only for a relatively short duration up to 60 h in a limited number of production phases during the year. Similar restrictions do not exist for porous rock storage facilities, which normally hold substantially larger quantities of working gas that is produced at lower rates. The working gas volume at a salt cavity storage site, on the other hand, may be increased by leaching an appropriate number of caverns.

Transmission system operators optimize their peak-shaving operations by employing both

Figure 36. Optimum production of gas from porous rock storage and salt cavern storage for peak shaving

porous rock and salt cavern storage facilities. The peaking service baseload is provided by the production of gas from porous rock facilities at relatively constant load, whereas caverns are used in periods of maximum demand. The optimum employment of storage caverns and storage reservoirs depends, of course, on supply and demand load patterns (see Fig. 36).

4.3. Distribution

Distribution systems take gas from regional supply centers and transport it to residential, commercial, and industrial users. These systems consist of high-pressure, medium-pressure, and low-pressure grids. Distribution systems tend to be operated at low load factors because they serve a market in which demand varies considerably. If most gas is used for heating, the grid is designed for peak load on a winter day.

Distribution grids have grown in most areas over the years because gasworks were built in many cities long before natural gas became available. For this reason, distribution grids consist of mains of different diameters and different materials laid in different years.

Old distribution lines often operate at 2 – 8 kPa, whereas new distribution mains are frequently designed for a working pressure of 100 kPa. Low-pressure distribution grids are normally tied into medium-pressure or high-pressure distribution systems from which they receive gas at special supply stations.

Since local distribution networks consist of mains cross-connected at numerous points, computers are required to predict flow in distribution lines. Early models and methods for solving these nonlinear patterns were proposed by Cross in 1936 and Mac Illroy in 1949 [110]. Substantial computing time is required for such a nonlinear model, which originally consisted of very few nodes in view of the limited performance of early computers. As data-processing technology progressed during the 1950s, network analysis techniques become more widely used. They are now state of the art and are employed as a matter of course in distribution system design. Modern software models all the details of distribution systems.

Many of the input data required for network analysis can be determined only by statistical methods and field tests. For example, statistics are necessary to predict system loads controlled by the demand of numerous gas users whose meters are usually read only once each year. Pipe roughness, which is crucial for the hydraulic behavior of the grid, must be measured in many cases because pipe properties depend on the year in which the distribution line was constructed.

Distribution networks must also be designed to handle peak loads that can be 10 or 15 times higher than the baseload. To optimize the economics of gas distribution, distribution system

capacity is regularly adapted to growing demand. Methods of increasing capacity include the following:

1) replacement of mains or laying of new lines;
2) increasing distribution system pressure often to a maximum of 10 kPa in old systems and installation of service regulators to lower the pressure to 2 kPa at which most appliances are operated; or
3) installation of new medium-pressure or high-pressure system stations to feed gas into the low-pressure grid.

Figure 37. Pipeline diameter as a function of working pressure for constant pipeline capacity (in relation to pipeline diameter for 2.5-kPa working pressure)

New governor stations to interconnect ring mains and distribution lines constitute a particularly effective method of increasing distribution grid capacity [111, 112]. Local distribution companies normally combine all three methods to optimize the economics of gas distribution. The new distribution lines that are increasingly being built to develop service in rural regions are designed mainly for a pressure of 100 kPa, because the higher distribution pressure substantially reduces pipeline diameter for the same pipeline capacity (see Fig. 37). In fact, high distribution pressures are often necessary to serve rural areas because 100-kPa distribution lines can transport gas over much longer distances.

5. Economic Aspects

Natural gas is the world's third most important energy source, behind oil and coal, covering ca. 23 % of the 1995 world energy demand.

Reserves. Proven world gas reserves at the end of 1995 totaled about 150×10^{12} $m^3(V_{st}$ i.e., standard cubic meter of natural gas at 15 °C and 101.3 kPa with a net calorific value of 35.2 MJ or 9.776 kW · h) (equivalent to 5171×10^{18} J or 134×10^9 t of oil), corresponding to ca. 95 % of proven oil reserves [113]. A geographical breakdown is shown in Table 13. These reserves equal about 55 years of current annual gross production.

In addition, ca. 222×10^{12} $m^3(V_{st})$ (equivalent to ca. 7770×10^{18} J or 200×10^9 t of oil [114]) has been identified as probable gas reserves. Including this figure, the total 1995 gas inventory equals approximately 135 years of current annual gross production.

Production. The world's 1995 gross gas production amounted to 2.75×10^{12} $m^3(V_{st})$ (95.15×10^{18} J or 2.4×10^9 t of oil), of which about 80 % was marketed. The rest covers reinjection, flaring, losses, etc. The total 1995 marketed volume of 2.21×10^{12} $m^3(V_{st})$, broken down into major geographic zones, is shown in Table 14.

Consumption. Consumption patterns in various regions of the world generally follow production profiles, as shown in Table 14. The Former Soviet Union and Eastern Europe as well as North America both produce and consume ca. 30 % of the world's annual natural gas availability.

International Trade. Although marginal compared to total consumption, a sizable trade over national borders has developed since 1960. Initial international deliveries were mainly to neighboring countries through pipelines, whereas shipments of LNG developed in the 1970s. Table 15 summarizes the natural gas volume traded internationally in 1995. Of the total of 395×10^9 $m^3(V_{st})$ (equivalent to 13×10^{18}

Table 13. World's proven natural gas reserves as of January 1, 1996 [113]

Area	10^{12} m^3(V_{st})	10^{18} J	%
North America	6.5	222	4.3

Asia, Oceania	213	1220
Total	2207	2207

Pricing. Except for a minor amount used as chemical feedstock, natural gas is primarily employed as clean heating fuel in industry, power plants, commercial installations, and households. To maintain its competitiveness versus alternative energies, natural gas prices for the final consumer are generally determined by prices of competitive fuels such as light heating oil, heavy fuel oil, coal, LPG, or electricity, with due consideration of the inherent environmental, handling and financial advantages of gas utilization.

Since gas transportation costs significantly exceed those of oil or other fuels, gas netbacks at the wellhead are generally lower than those for crude oil. To compensate for the heavy front-end investment in production, purification, and transportation facilities, a large share of internationally traded natural gas is normally sold by producers under long-term contracts of up to 35 years' duration, which oblige sellers to make predetermined annual quantities available, whereas buyers are obliged to offtake certain minimum quantities per year (take-or-pay obligation: usually 80 % of availability). Prices of such long-term gas deliveries are generally tied to official international crude or fuel oil quotations.

6. Testing and Analysis

Natural gas analysis can be divided into two areas: chemical analysis of the composition, and

Table 15. International gas trade in 1995 [10^9 m^3(V_{ST})]

Supplies from	Imports to

determination of the physical properties. Chemical analysis methods for natural gas are summarized in [115, 116]. Instructions for both the chemical analysis and determination of physical properties for natural gases are given in [116].

For the analysis and quality control of gases, see also → Gas Production.

6.1. Analysis of Natural Gas Composition

The most important method for chemical analysis of natural gas is gas chromatography [117 – 123]. Sampling must be carried out before the gas can be analyzed.

6.1.1. Sampling

Glass equipment is mainly used for sampling because glass is not attacked by any component of natural gas and does not affect the composition of the gas [124]. Vessels with two taps (see Fig. 38) are used, which must be completely dry. The gas to be analyzed is first passed through the sampling vessel to completely displace the air from it. Both taps are then closed so that the sample is contained in the vessel. The sample should always be under slight overpressure, so that no air is drawn into the vessel even if the taps are not closed tightly.

Figure 38. Sampling vessel

6.1.2. Gas Chromatography

Gas chromatography has developed since 1952 and has replaced the Orsat method, previously used for analysis of natural gas (→ Gas Production, Chap. 8.2.2.1). Gas chromatography is the preferred method for most gas analyses. The analysis of natural gas by gas chromatography has been standardized in ASTM D-1945. In gas chromatography, the gas to be analyzed is transported by a carrier gas stream (usually helium or argon) through a separating column. Carbon dioxide may also be used as carrier gas according to the Janak (→ Gas Production, Chap. 8.2.2.1), [125]. Figure 39 shows the setup for gas chromatography [120] and Figure 40 an example of a gas chromatogram of natural gas [120]. The separating column is filled with a molecular sieve or with Chromosorb.

Table 16. Standard reference mixtures for the chromatographic analysis of natural gas

Component	Lean gas, mol %	Rich gas, mol %
Methane	85.0	74.0
Ethane	6.0	10.0
Propane	4.0	7.0
n-Butane	2.0	3.0
Isobutane	2.0	3.0
n-Pentane	0.5	1.0
2,2 Dimethylpropane	0.5	1.0
Isopentane	0.5	1.0
Hexanes and higher hydrocarbons	0.1	0.2
Nitrogen	4.0	0.5
Carbon dioxide	1.0	1.0
Helium	1.0	0.5
Hydrogen	3.0	0.5

Thermal conductivity detectors and flame ionization detectors are most commonly used, mass spectrometers may also be used for detection [119]. In some cases, two columns must be used – one for the separation of hydrocarbons, the other (for a new sample) mainly for determination of nitrogen and oxygen. Standard reference mixtures are used for two gas qualities: lean gas (i.e., gas containing few or no condensable hydrocarbons and thus having a lower calorific value) and rich gas (i.e., gas containing a higher amount of condensable hydrocarbons and thus having a higher calorific value) (see Table 16).

6.1.3. Analysis of Nonhydrocarbons

Natural gases can contain various gases apart from hydrocarbons: nitrogen, carbon dioxide,

Figure 39. Gas chromatograph
a) Carrier gas; b) Regulating valve; c) Manometer; d) Chart recorder; e) Air thermostat; f) Separating column; g) Thermal conductivity detector; h) Flow meter; i) Three-way tap; j) Trap

and noble gases can be determined during gas chromatographic analysis of the hydrocarbons. A gas chromatographic analysis method for non-condensable gases in light hydrocarbons is given in [126]. The content of water, sulfur compounds, and mercury may also be determined.

Figure 40. Gas chromatogram of natural gas

Determination of Water. Water must be removed from natural gas to prevent its condensation and to avoid the formation of gas hydrates [127] (see Section 1.2). Low water content of the order of milligrams per cubic meter can be titrated according to the classical *Karl – Fischer method*, in which water reacts with iodine in an alcoholic solution of sulfur dioxide and pyridine [128]. The iodine can also be determined coulometrically. Water can be determined gravimetrically by absorption using a desiccant such as magnesium perchlorate. A variety of *hygrometers* [129] measure, for example, the variation in the conductivity of glycerol with water content. Dew point measurements (see Section 6.2.4) indirectly give the water content.

Determination of Sulfur Compounds. Natural gases can contain hydrogen sulfide and occasionally mercaptans (see Section 2.4). The total sulfur content can be determined by combustion with excess air or oxygen. Either the sulfur dioxide formed can be determined, e.g., by means of a coulometric titration, or the combustion products can be absorbed in an oxidizing solution and the sulfuric acid formed is determined.

Hydrogen sulfide can be detected qualitatively using lead acetate producing a black coloration due to the formation of lead sulfide.

In the ASTM standard test method a measured volume of gas is bubbled through two solutions – first a neutral cadmium sulfate solution and then a basic cadmium sulfate solution [130]. Hydrogen sulfide is found in the neutral solution and the mercaptans in the basic solution. Hydrogen sulfide and mercaptans are then determined iodometrically.

Determination of Trace Components. Heavy metals, especially mercury (see Section

2.3.2), are the most important trace components. There are at present no standard determination methods; atomic absorption spectroscopy (AAS) is usually used.

6.2. Determination of Physical Properties

Natural gases are characterized and classified according to their physical properties. The *Wobbe index* (W) (see Section 1.3.2) is the most important characteristic for the classification of natural gases and they are divided into two groups: group L (low Wobbe index) and group H (high Wobbe index). The Wobbe index is calculated according to

$$W_S = H_S/\sqrt{d}\ (\mathrm{MJ/m^3}),$$

where H_S is the gross calorific value and d the relative density (based on air). In addition to the more commonly used superior Wobbe index W_S, the inferior Wobbe index W_I can be calculated, whereby the inferior calorific value H_I is used instead of H_S. The Wobbe indices indicate gas quality for combustion.

Usually the Wobbe index is calculated from H_S and d. Automated calorimeters are available for its direct determination (Wobbe recorders) which use a gas stream that is adjusted so that the flow rate is proportional to $1/\sqrt{d}$.

Important physical properties of natural gas include the following:

Density
Calorific value
Molecular mass
Dew point

6.2.1. Density

Density can be measured with a *gas density balance*. The method is based on the different buoyancy of a nitrogen-filled glass sphere suspended from a balance in various test gases [131]. The gas to be measured and nitrogen should have the same temperature and pressure. Instruments of this type also allow continuous measurement and recording of gas density in a gas stream.

A particularly reliable method is to weigh a specific volume of gas in a glass flask (e.g., a *Chancel flask* according to IP 59). Either the density of the gas (mass per unit volume) or the relative density d (the ratio of the density of the gas to that of dry air) is determined. The density and relative density can also be calculated from the composition determined by gas analysis [132].

6.2.2. Calorific Value

The calorific value in MJ/m^3 can be determined in three ways: (1) directly by combustion of the gas at constant pressure in a gas calorimeter, (2) by stoichiometric combustion and measurement of the gas : air ratio, and (3) by calculation from the values obtained from gas analysis.

The principle of *continuous recording gas calorimeters* is combustion of a controlled stream of gas, followed by heat exchange between the combustion gases and a liquid, whose temperature increase is measured and recorded [133]. This method is the most widely used. *Discontinuous gas calorimeters* involve combustion of a specific amount of gas and the resulting temperature increase is measured directly.

6.2.3. Molecular Mass

The molecular mass of natural gas is calculated as an average value from the concentrations determined by gas analysis and the molecular masses of the components (see Chap. 1).

6.2.4. Dew Point

In order to avoid condensation of water, the gas temperature should not drop below the dew point of the water contained in the gas. The dew point can be determined directly by passing a constant stream of gas over a polished metal mirror that is slowly cooled. The dew point is the temperature at which the first signs of condensation appear on the mirror. These methods can be used for gases under pressures of up to 10 MPa. Automated instruments using photocells are also employed [134]. If the gas stream contains easily condensable hydrocarbons, then these must be washed out by passing the gas through high-boiling liquid paraffin prior to determination.

1. Introduction

Nematicides (also called nematocides) are plant protection agents (i.e., pesticides) used to control plant-parasitic nematodes. The growing use of intensive cropping and production methods in agriculture means that plant-parasitic nematodes are becoming an increasingly important yield-limiting factor in many crops. Nematicides are an indispensable part of nematode management in modern agriculture.

This article describes plant-parasitic nematodes and their control, with particular regard to nematicides. For agents used against human-parasitic and animal-parasitic nematodes, see → Anthelmintics, Vetinary Drugs.

2. Plant-Parasitic Nematodes

Nematodes are small, wormlike, unsegmented organisms. On account of their body shape and undulatory movements, nematodes are also termed eelworms.

2.1. Characteristics of Plant-Parasitic Nematodes

Classification. Nematodes belong to the phylum Nematoda. The majority of the currently described nematode species (ca. 15 000) live in freshwater or marine habitats, or as bacterial or fungal feeders in the soil. Numerous species attack humans and animals; about 4300 species are plant parasites.

Morphology and Anatomy. Plant-parasitic nematodes are small, transparent, cylindrical organisms (length ca. 300 – 4000 µm, width 15 – 35 µm). All plant-parasitic nematodes have a stylet, generally in the form of a hollow needle (exception: *Trichodorus* sp.), which is used to puncture the plant cells, inject saliva, and suck out part of the cell contents. Nematodes only have longitudinal muscles and can therefore only execute an undulatory movement. They do not have a vascular system or special respiratory organs.

Life Cycle. The life cycle of all plant-parasitic nematodes is essentially the same. After development of the embryo, the first molt generally occurs in the egg. The hatched larvae are mobile and search for a host plant. Nematodes pass through four larval stages before developing into the adult form. Both sexual and parthenogenetic reproduction occur. The reproduction rate is species dependent, but also depends on environmental factors (e.g., soil, temperature, host plant, competition between and among species). A root-knot nematode female can, for example, produce a total of 500 eggs, several generations can develop per year. Other

nematode species such as *Globodera rostochiensis* produce only one generation per year. Many nematode species have a dormant phase, which enables them to survive for very long periods without a host plant. Under favorable conditions, some cyst-forming nematodes can remain viable for up to ten years in the absence of suitable host plants.

Mode of Parasitism. The parasitic behavior of plant nematodes varies widely. For example, they can damage plant parts that grow aboveground, (e.g., flowering parts by *Anguina tritici*, leaves and buds by *Aphelenchoides* sp., as well as stalks and leaves by *Ditylenchus* sp.).

Of greater importance, however, are nematodes that damage plant parts below ground. Nonsedentary root nematodes migrate from one feeding site to the next. Ectoparasites normally pierce the roots from outside, whereas endoparasitic root nematodes can enter the root tissue and feed from within.

Sedentary root nematodes generally penetrate the root tissue. They induce a feeding cell system, on which they depend until they are sexually mature and discontinue feeding.

Population Density and Distribution. The soil nematode population constitutes a significant proportion of the mesofauna (animals of medium size), particularly in tropical and subtropical regions. The nematode population can account for up to 5 % of the biomass of the soil (i.e., 100×10^6 nematodes per square meter), but often only a very small proportion is plant parasitic.

It is not possible to give any generally valid information on damage thresholds because they vary according to the nematode species, host plant, temperature, and many local parameters. For example, although only 20 *Meloidogyne arenaria* larvae per 100 mL of soil may produce severe yield losses in tomatoes, under certain conditions about 300 *Xiphinema* sp. per 100 mL of soil do not cause visible damage.

Since nematodes can only migrate over very small distances, active propagation is limited. Passive propagation (i.e., dispersion by harvest residues, soil cultivation, wind, contaminated machinery, water, seeds, and harvested crops) plays an important role in establishing a new infection.

2.2. Plant Damage

Physiological Basis. The primary sucking damage caused by nematodes and the associated removal of the cell contents are of comparatively minor importance. Damage is primarily due to the subsequent plant reactions: to the secretion of saliva such as root galling (swelling), breakdown of root tissue, and increased formation of lateral roots. Altered root growth as a result of nematode infestation leads in turn to reduced water and nutrient uptake. Young plants react particularly sensitively to nematode infestation. The mechanical tissue injury caused by some migrating nematodes as well as the commonly occurring interactions with fungal and bacterial pathogens can also lead to considerable yield losses. Some nematode species (e.g., *Xiphinema*, *Longidorus*, *Paralongidorus*, *Trichodorus*, *Paratrichodorus*) also act as vectors for viruses responsible for yield losses and cause damage as a result of feeding.

Symptoms. Plant-parasitic nematodes only rarely produce characteristic symptoms on above-ground plant parts; typical symptoms can be more readily recognized on and in the roots:

root galls (*Meloidogyne*)
cysts (*Heterodera, Globodera*)
lesions (*Pratylenchus, Radopholus*)
stubby root (*Trichodorus*)

For an accurate diagnosis, special extraction and detection methods are often necessary [16], [17, pp. 13 – 46] .

Damage to Cultivated Plants and Crops. It is difficult to estimate the crop losses caused by nematodes; results differ considerably. Worldwide annual losses due to nematodes were estimated at 12 % in 1987, corresponding to a value of $\$ 77 \times 10^9$ (averaged over all important cultivated plants) [18]. The necessity for nematode control can be assessed comparatively accurately on the basis of estimates of nematicide use: the overall nematicide market, including fumigants, was ca. $\$ 485 \times 10^6$ in 1989 [19] – only about 2 % of the total agrochemical market. Important areas of use of nematicides are the protection of vegetables, potatoes, tobacco, bananas, berries, soft fruits, ornamental plants, peanuts, beet, citrus fruits, and cotton.

The gall-forming, sedentary *Meloidogyne* species are by far the most important nematodes in terms of their effects on crop losses, especially in warmer climates. These roughly 70 different species can infest all important crops; they produce root galls that affect the growth of the root system.

The cyst-forming, sedentary nematode genera *Globodera* and *Heterodera* are primarily of importance in temperate climatic zones, and in some species have a narrow host spectrum. The females are transformed into tough, egg-filled cysts. The eggs can survive in the soil for a very long time. Important examples are *Heterodera avenae* (e.g., cereals), *H. glycines* (e.g., soybean), *H. schachtii* (e.g., sugarbeet), *H. tabacum* (e.g., tobacco), *H. trifolii* (e.g., clover), *Globodera rostochiensis*, and *G. pallida* (e.g., potatoes, tomatoes).

The "citrus nematode" (*Tylenchulus semipenetrans* in citrus fruits), the "lesion nematode" (*Pratylenchus* in cereals, vegetables, fruit, ornamental plants), and the "burrowing nematode" (*Radopholus* in bananas) are further examples of important endoparasitic root nematodes.

"Stem and bulb nematodes" (*Ditylenchus*) cause delayed plant germination. In cases of serious infestation they also cause the death of young plants and lesions on the leaves and stems of onions, strawberries, and many types of ornamental plants.

"Leaf nematodes" (*Aphelenchoides* sp.) and "seed – gall nematodes" (*Anguina* sp.) are of only minor importance.

3. Nematode Management

The object of nematode management is to restrict the spread of plant-parasitic nematodes or keep their population below the threshold for economically significant damage. Control strategies include both chemical and nonchemical measures.

3.1. Nonchemical Measures

Quarantine measures and hygiene are the only preventive measures of any great importance because nematodes are mainly spread and transmitted by passive transport. In modern agriculture with international exchange of plant material and harvested crops, such measures may be insufficient.

Cultivation measures include the maintenance of fallow land or intensified cultivation of nematode nonhost plants or plants with nematicidal properties in crop rotation. These measures are only effective for controlling nematodes with a narrow host spectrum, they are seldom economical under intensive cultivation conditions.

Physical measures are successful in some cases: flooding of arable land; heat sterilization of soils by steam, ultrasound, or "solarization" in which polyethylene tarps are used to trap solar energy; and hot-water treatment of seeds and plant material. On account of their high costs, these measures are used only for a few high-value crops.

Varieties of crops such as potatoes, tomatoes, tobacco, and soybeans exist that are considered to be resistant to certain nematode species. Although the development of *resistant varieties* involves a great deal of time and effort, it is one of the most cost-effective control measures for the user. However, the frequent use of resistant varieties entails the long-term danger of loss of resistance due to nematode pathotypes or the rapid proliferation of nematode species that are not affected by the resistant plant.

A large number of *nematode antagonists* are known (fungi, bacteria, viruses, and protozoa). Their widescale use is, however, limited by a narrow host spectrum, problematic mass production, lack of storage-stable formulations, high application rates, and unpredictable action.

3.2. Chemical Measures

Since the nonchemical measures for nematode control are currently only of limited use, chemical control is unavoidable in many cultivated plants and crops.

Although chemical nematode control had already been used to a limited extent at the end of the nineteenth century (e.g., use of carbon disulfide), it was only from about the mid-1940s that it achieved greater importance with the use of chloropicrin, a mixture of 1,2-dichloropropane and 1,3-dichloropropene (D-D), 1,2-dibromo-3-

chloropropane (DBCP), and 1,2-dibromoethane (EDB).

The nematicides used nowadays can be subdivided into four groups:

1) Halogenated aliphatic hydrocarbons
2) Compounds related to methylisothiocyanates
3) Organophosphates
4) Carbamates

Groups 1 and 2 constitute the first generation of nematicides. On account of their low boiling points they are classified as *fumigants*. Compounds such as methyl bromide, chloropicrin, and methyl isothiocyanate also have a pronounced soil-insecticidal, fungicidal, or herbicidal action in addition to their nematicidal action. Fumigants are usually injected as a gas or liquid into the soil (required amount 200 – 1000 L/ha). On account of their high vapor pressure, the substances are distributed in the top soil layer and kill both free-living nematode stages as well as the eggs. Nematodes in deeper soil layers are not completely killed, and the nematode population may recover. Plant compatibility of these substances is often low and should be borne in mind. Use on established crops is not possible in many cases. Waiting periods of 10 – 14 d are generally necessary. Fumigants have a simple chemical structure and are therefore inexpensive. Despite the high doses required and the technically complicated mode of application, economical use is often possible. In quantitative terms fumigants account for more than 50 % of nematode control worldwide.

Organophosphates and carbamates have been used for nematode control since the early 1960s (second-generation nematicides). They are employed as granulate or liquid formulations in amounts of ca. 2 – 10 kg/ha. The active ingredients are generally water-soluble, and can thus be distributed in the soil capillary system. They often have supplementary insecticidal action. They are well tolerated by plants and can thus be used on seeds, seedlings, and established crops. These nematicides are applied as a band, in furrows, or as a broadcast application; incorporation of the products into the upper layer of the soil promotes their distribution. With some crops, application in a low-pressure irrigation system (e.g., drip irrigation) or treatment of nursery seedlings or bulbs may also be employed. Nematodes are often not killed, but only paralyzed or disoriented depending on the concentration of the active substance in the soil. The effect is ascribed mainly to cholinesterase inhibition which, in turn, interferes with nervous transmission.

Although fumigants are currently still extremely important worldwide in chemical nematode control, their use will probably decrease. Possible reasons for this include the very high amounts applied, the relatively expensive and sophisticated application techniques, translocation into the groundwater (e.g., DBCP, EDB, D-D), and toxicological considerations (e.g., for DBCP: male sterility, carcinogenesis; EDB is banned in the USA). The carbamates and phosphorus esters also exhibit disadvantages: high acute mammalian toxicity, in some cases high avian toxicity, and translocation into the groundwater are becoming increasingly significant.

Third-generation nematicides are subject to stringent requirements, which means that their development is becoming increasingly difficult and expensive. The wide usage requires selective agents that act solely against nematicides. New groups of active substances, possibly with new modes of action, should exhibit a favorable toxicological profile and should also have advantages as regards application and environmental compatibility. For example, use of nematicides as seed treatments would reduce the required dose; after foliar application, it is highly desirable that the nematicide is transported basipetally to the roots (reduction of leaching).

4. Individual Nematicides

In the following only nematicides still used frequently are given, others, for reasons stated above, are only mentioned briefly.

4.1. Fumigants and Other Agents

Carbon disulfide [*75-15-0*], CS_2, has been used as a fumigant against insects and nematodes.

Chloropicrin [*76-06-2*], trichloronitromethane, CCl_3NO_2, M_r 164.4, *mp* − 64 °C, *bp* 112.4 °C,

vapor pressure 3.2 kPa (25 °C), is a colorless liquid with lachrymatory action which is fairly soluble in water, and miscible with most organic solvents [20, p. 226].

Cl_3CNO_2

Chloropicrin is formed by chlorinating nitromethane or picric acid with alkali metal or alkaline earth hypochlorites or by treating acetone with concentrated nitric and hydrochloric acids [21].

Chloropicrin has insecticidal and nematicidal properties. It is used as a soil fumigant to control nematodes and other soil-dwelling pests. It is highly toxic to both plants and animals. It has an extremely irritating effect on the mucous membranes and has been used as tear gas.
Trade Names. Chlor-O-Pic (Great Lakes); Dorochlor (Mitsui Toatsu).

Dazomet [*533-74-4*], 3,5-dimethyl-1,3,5-thiadiazinane-2-thione, $C_5H_{10}N_2S_2$, M_r 162.3, *mp* 104 – 105 °C, vapor pressure 0.37 mPa (20 °C), forms colorless crystals which are fairly soluble in water and diethyl ether, and readily soluble in cyclohexane, chloroform, acetone, benzene, and ethanol [20, p. 335].

Dazomet is produced by reaction of methylammonium *N*-methyldithiocarbamate with formaldehyde [22]. Dazomet is sensitive to moisture and heat (> 35 °C); acid hydrolysis yields carbon disulfide. In the ground Dazomet decomposes into methyl(methylaminomethyl)dithiocarbamic acid, followed by methyl isothiocyanate, which is the compound responsible for the fungicidal, bactericidal, and nematicidal action [23].

Dazomet is used as a soil sterilant to control nematodes, and as a slimicide in pulp and paper manufacture, and as a preservative in adhesives and glues. Dazomet is also used as a herbicide, fungicide, and insecticide.
Trade Names. Basamid (BASF), Dazoberg (Diachem).

1,2-Dibromo-3-chloropropane [*96-12-8*] was used as a nematicide before sowing or planting.

Ethylene dibromide [*106-93-4*], 1,2-dibromoethane, $C_2H_4Br_2$, M_r 187.9, *mp* 9.3 °C, *bp* 131.5 °C, vapor pressure 1.5 kPa (25 °C), is a colorless liquid which is fairly soluble in water, soluble in diethyl ether, ethanol, and most common organic solvents [20, p. 490].

$BrCH_2CH_2Br$

Ethylene dibromide is produced by the uncatalyzed addition of bromine to ethylene (→ Bromine Compounds, Chap. 1.4.1.)[24]. Ethylene dibromide is used as a fumigant to control nematodes, wireworms, and other soil pests, and in fumigation of mills, warehouses, and households. It is also used as an insecticide.
Trade Name. Dibrome (United Phosphorus).

1,3-Dichloropropene [*542-75-6*], $C_3H_4Cl_2$, M_r 111.0, *bp* 104.3 °C (*Z* isomer), 112 °C (*E* isomer), 108 °C (isomer mixture), is a colorless-to-amber liquid which is fairly soluble in water, miscible with hydrocarbons, halogenated solvents, esters, and ketones [20, p. 366].

E isomer
